Supporting Information

ABSTRACT: The reaction of the gold polymers containing bipyridyl and terpyridyl units, $[\text{Au}(\text{C}\equiv\text{CC}_{15}\text{H}_{10}\text{N}_3)]_n$ and $[\text{Au}(\text{C}\equiv\text{CC}_{10}\text{H}_7\text{N}_2)]_m$, with the water-soluble phosphines 1,3,5-triaza-7-phosphatricyclo[3.3.1.1.3.7]decane and 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]nonane gives rise to the formation of four gold(I) alkynyl complexes that self-assemble in water (H_2O) and dimethyl sulfoxide (DMSO), through different intermolecular interactions, with an impact on the observed luminescence displayed by the supramolecular assemblies. A detailed analysis carried out by NMR studies performed in different DMSO/deuterated H_2O mixtures indicates the presence of two different assembly modes in the aggregates: (i) chain assemblies, which are based mainly on aurophilic interactions, and (ii) stacked assemblies, which are based on $\text{Au}\cdots\pi$ and $\pi\cdots\pi$ interactions. These different supramolecular environments can also be detected by their intrinsic optical properties (differences in absorption and emission spectra) and are predicted by the changes in the relative binding energy from density functional theory calculations carried out in DMSO and H_2O . Small-angle X-ray scattering (SAXS) experiments performed in the same mixture of solvents are in agreement with the formation of aggregates in all cases. The aromatic units chosen, bipyridine and terpyridine, allow the use of external stimuli to reversibly change the aggregation state of the supramolecular assemblies. Interaction with the Zn^{2+} cation is observed to disassemble the aggregates, while encapsulating agents competing for Zn^{2+} complexation revert the process to the aggregation stage, as verified by SAXS and NMR. The adaptive nature of the supramolecular assemblies to the metal-ion content is accompanied by significant changes in the absorption and emission spectra, signaling the aggregation state and also the content on Zn^{2+} .

INTRODUCTION

The self-assembly of small molecules by the establishment of noncovalent interactions has received great attention in the past decade as a way to build supramolecular structures with a large number of specific functions and morphologies.^{1–4} As a result, supramolecular chemistry has matured from a conceptually marvelous scientific curiosity to a technologically relevant science encompassing a broad area of advanced materials.⁵ Within this field, gold(I) complexes represent an emerging area of investigation in the last years because they show weak $\text{Au}^1\cdots\text{Au}^1$ interactions that can modulate and govern the resulting assemblies and properties in very different potential applications.^{6,7} It was recently shown that small molecules of the type R-gold(I) alkynylpyridine, where R is a water-soluble

phosphine (compounds A and B in Chart 1), self-assemble to form long fibers and hydrogels through intermolecular π -stacking and metallophilic interactions.^{8,9} Replacing the pyridine moiety by a different aromatic unit such as coumarin (compound C in Chart 1) does not hamper the assembling ability of these molecules.¹⁰ On the other hand, the introduction of a positive charge on the chemical structure either at the phosphine (complexes 1 and 4 in Chart 1) or at the pyridyl unit (complexes 2, 3, 5, and 6) switches the fibrillar self-assembly into rods, spherical vesicles, or squarelike morphologies.¹¹

Chart 1. Molecular Structures of the Gold(I) Alkynyl Complexes Previously Studied

Novel supramolecular nanostructures constituted by the noncovalent self-organization of small metallophilic molecules with tunable properties are underexplored within the field of self-assembling materials. Research interest has increased in the last years in the construction of stimuli-responsive metallosupramolecular architectures with diverse sizes, shapes, and symmetries because of their promising applications such as molecular transporting devices, chemosensors, optoelectronic devices, drug delivery, tissue engineering, biomaterials, surface science, displays, etc.^{5,12–16} Stimuli-responsive systems are capable of modulating their behavior in a differential manner depending on the external stimulus to which they are exposed, being a considerable challenge for supramolecular chemists.

The modular chemistry of gold(I) alkynyl complexes, furthermore, allows for a rational design where solubility and function can be added to program the supramolecular assembly into nanostructures that can be tuned by changes in the charge or polarity, among others.

In this work, we extend the development of these small molecules by adding a chelating unit able to trigger the assembly/disassembly process by external stimuli (e.g., cations and chelating molecules). At the same time, the increase in the number of aromatic rings will allow a change in the balance between Au...Au and $\pi\cdots\pi$ interactions, which will impact the stability of the aggregates. Complexation with cations will significantly change the electrostatic balance of the assemblies, leading to dissociation. The disassembly can be reversed by the addition of molecules that compete for the metal cation, leading to reassembly of the nanostructures.

EXPERIMENTAL SECTION

General Procedures. All manipulations have been performed under prepurified N₂ using standard Schlenk techniques. All solvents have been distilled from appropriated drying agents. Commercial reagents 1,3,5-triaza-7-phosphatricyclo[3.3.1.1^{3,7}]decane (PTA; 97%, Aldrich) and 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]nonane (DAPTA; 97%, Aldrich) have been used as received. Literature methods have been used to prepare 5-ethynyl-2,2'-bipyridine,¹⁷ 4'-ethynyl-2,2',6',2''-terpyridine,¹⁸ [Au(C≡CC₁₅H₁₀N₃)]_n¹⁹ and [Au(C≡CC₁₀H₇N₂)]_n²⁰

Physical Measurements. IR spectra have been recorded on a Nicolet 520 Fourier transform infrared spectrophotometer. ¹H [δ (TMS) = 0.0 ppm] and ³¹P{¹H} [δ (85% H₃PO₄) = 0.0 ppm] NMR spectra have been obtained on Varian Mercury 400 and Bruker 400 spectrometers. One- and two-dimensional (1D and 2D) NMR experiments were performed also at 298 K on a 500 MHz Bruker AVANCEIII-HD spectrometer equipped with a z-gradient (65.7 G/cm) inverse TCI cryoprobe. The gradient strength was calibrated using the diffusion coefficient of water (H₂O) in a standard solution of 0.1 mg/mL GdCl₃, 0.1% 4,4-dimethyl-4-silapentane-1-sulfonic acid, and

1% H₂O in deuterated H₂O (D₂O). Samples **2a** and **2b** were dissolved in the corresponding deuterated solvent containing 3-(trimethylsilyl)propionic-2,2,3,3-*d*₄ acid sodium salt (TSP-*d*₄). TSP-*d*₄ was used as an internal standard both for calibrating the ¹H and ¹³C chemical shifts and for estimating the relative concentration changes upon aggregation. Bruker TopSpin 3.5spl6 standard pulse sequences were used for the 1D and 2D experiments. To obtain the highest receiver gain and to apply the minimum amount of scans and increments using low sample concentrations (≤ 1 mM), the reduction of residual water in the NMR spectra (coming from the sample and/or on deuterated solvents) was needed, so pulse sequences with a soft suppression of the water resonance were used. 1D ¹H NMR experiments were acquired using the zgpg30 pulse sequence, which incorporates water suppression using excitation sculpting with gradients and perfect echo. For 2D ¹H–¹H NMR experiments, excitation sculpting for ¹H–¹H NOESY (noesygpph pulse program) and 3–9–19 pulse train for DOSY (stebgp1s19 pulse program) were applied for water suppression. 2D ¹H–¹³C (HSQC and HMQC) experiments were also acquired. Spin–lattice (*T*₁) and spin–spin (*T*₂) relaxation times were measured for complex **2b** using a standard inversion–recovery pulse sequence for *T*₁ and PROJECT-CPMG²¹ for *T*₂.

2D DOSY²² experiments were performed using a stimulated-echo sequence incorporating bipolar gradient pulses and one spoil gradient. The gradient strength was logarithmically incremented in 18–24 steps from 5 to 98% of its maximum value. Diffusion times and gradient pulse durations were optimized for each experiment. Typically, diffusion times between 60 and 120 ms and bipolar rectangular gradient pulses of 2.0 ms were employed. Diffusion NMR data were processed and represented using the free software DOSY Toolbox.²³ The translational diffusion coefficient obtained for different samples was used to estimate the “apparent” sizes of the gold(I) complexes in different solvent compositions. For calculation of the hydrodynamic radii, the diffusion coefficients were obtained from the monoexponential fitting of the integral values versus gradient strength using the TopSpin 3.5spl6 relaxation module. When calculating and interpreting the values of the hydrodynamic radii, we have taken into account two facts: (1) the Stokes–Einstein equation is only valid for spherical particles with sizes larger than the solvent molecules; (2) the effects of chemical exchange in diffusion spectra.²² In our case, for DMSO-*d*₆ and DMSO-*d*₆ with low amounts of D₂O, we expected to have mainly monomer or dimer molecules in solutions, so our gold(I) complexes have slightly larger sizes than the solvent. Therefore, for our *r*_H calculations, we followed the method described by Macchioni et al.²⁴ using the expression of factor *c* as a function of *r*_{sol}/*r*_H derived by Chen et al.²⁵ and the approximation that our complexes were spherical.

Positive-mode electrospray ionization mass spectrometry [ESI-MS(+)] spectra were recorded on a Fisons VG Quatro spectrometer. Absorption spectra were recorded on a Varian Cary 100 Bio UV spectrophotometer and emission spectra on Horiba-Jobin-Yvon SPEX Fluorolog 3.22 and Nanolog spectrofluorimeters. Fluorescence microscopy was recorded on a Zeiss Axioplan 2ie imaging microscope equipped with a Nikon DXM1200F digital camera and a Leica DMIRB

fluorescence microscope. Optical microscopy images were acquired on a Leica ICC50 W microscope. Dynamic light scattering (DLS) measurements were carried out on a Horiba SZ-100 nanoparticle analyzer instrument operating at 22 °C.

Small-Angle X-ray Scattering (SAXS). SAXS was performed on the NCD beamline at the ALBA Synchrotron at 12.4 keV, and the distance sample/detector was 2.2 m to cover the range of momentum transfer of $0.09 < q \text{ (nm}^{-1}\text{)} < 5.6$. The data were collected on an ImXPad S1400 detector with a pixel size of $130.0 \times 130.0 \mu\text{m}^2$. The exposure time was 10 s. The q -axis calibration was obtained by measuring silver behenate.²⁶ The program *pyFAI*²⁷ was used to integrate the 2D SAXS data into 1D data.

The data were then subtracted by the background using *PRIMUS* software.²⁸ The maximum particle dimension D_{max} and the pair-distance distribution function $P(r)$ were determined with *GNOM*.²⁹ The low-resolution structure of the aggregates was reconstructed ab initio from the initial portions of the scattering patterns using the program *DAMMIN*.³⁰

Solutions of 1×10^{-4} and 1×10^{-5} M of complexes **1a**, **1b**, **2a**, and **2b** were prepared in different H₂O/dimethyl sulfoxide (DMSO) mixtures of 0% H₂O to 100% (0, 25, 50, 75, and 90%) DMSO.

Synthesis of [Au(C≡CC₁₅H₁₀N₃)(PTA)] (1a). Solid PTA (21 mg, 0.13 mmol) was added to a suspension of [Au(C≡CC₁₅H₁₀N₃)]_n (60 mg, 0.13 mmol) in CH₂Cl₂ (20 mL). After 45 min of stirring at room temperature, the resulting pale-yellow solution was concentrated (5 mL), and *n*-hexane (15 mL) was added to precipitate a pale-yellow solid (66 mg, 81%). ³¹P NMR (161.9 MHz, CDCl₃, ppm): −12.8. ¹H NMR (400 MHz, CDCl₃, 298 K, ppm): 8.62 (dq, $J = 4.8 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 2H, H₉), 8.53 (dt, $J = 12.0 \text{ Hz}$, $J = 1.2 \text{ Hz}$, 2H, H₁₂), 8.46 (s, 2H, H₃ + H₅), 7.84 (td, $J = 11.9 \text{ Hz}$, $J = 1.4 \text{ Hz}$, 2H, H₁₁), 7.30 (ddd, $J = 12.0 \text{ Hz}$, $J = 4.8 \text{ Hz}$, 2H, H₁₀), 4.60–4.48 (AB q, $J = 13.0 \text{ Hz}$, 6H, NCH₂N), 4.30 (s, 6H, NCH₂P). IR (KBr, cm^{−1}): 3425 (C–H), 2114 (C≡C), 1636 (C=N). ESI-MS(+): m/z 611.137 ([M + H]⁺); calcd m/z 611.139, 1243.250 ([2M + Na]⁺); calcd m/z 1243.252).

Synthesis of [Au(C≡CC₁₅H₁₀N₃)(DAPTA)] (1b). Solid DAPTA (30 mg, 0.13 mmol) was added to a suspension of [Au(C≡CC₁₅H₁₀N₃)]_n (60 mg, 0.13 mmol) in CH₂Cl₂ (20 mL). After 45 min of stirring at room temperature, the resulting pale-yellow solution was concentrated (10 mL), and *n*-hexane (10 mL) was added to precipitate a pale-yellow solid (75 mg, 85%). ³¹P NMR (161.9 MHz, CDCl₃, ppm): −10.2. ¹H NMR (400 MHz, CDCl₃, ppm): 8.68 (dq, $J = 5.0 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 2H, H₉), 8.56 (dt, $J = 12.0 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 2H, H₁₂), 8.48 (s, 2H, H₃ + H₅), 7.82 (td, $J = 11.8 \text{ Hz}$, $J = 1.6 \text{ Hz}$, 2H, H₁₁), 7.30 (ddd, $J = 12.0 \text{ Hz}$, $J = 4.8 \text{ Hz}$, 2H, H₁₀), 5.78 (d, $J = 20.0 \text{ Hz}$, 1H, H_{19a}, NCH₂N), 5.66 (dd, $J = 20.0 \text{ Hz}$, $J = 12.0 \text{ Hz}$, 1H, H_{23a}, NCH₂P), 4.94 (d, $J = 16.0 \text{ Hz}$, 1H, H_{21a}, NCH₂N), 4.70–4.64 (m, 2H, H_{17a}, NCH₂P, + H_{21b}, NCH₂N), 4.15 (dt, $J = 20.0 \text{ Hz}$, $J = 4.0 \text{ Hz}$, 1H, H_{17b}, NCH₂P), 4.06 (d, $J = 20.0 \text{ Hz}$, 1H, H_{19b}, NCH₂N), 3.87 (s, 2H, H₂₄, NCH₂P), 3.57 (dt, $J = 20.0/4.0 \text{ Hz}$, 1H, H_{23b}, NCH₂P), 2.17 (s, 6H, COCH₃). IR (KBr, cm^{−1}): 3441 (C–H), 2116 (C≡C), 1640 (C=N). ESI-MS(+): m/z 683.158 ([M + H]⁺); calcd m/z 683.160, 705.139 ([M + Na]⁺); calcd m/z 705.142).

Synthesis of [Au(C≡CC₁₀H₇N₂)(PTA)] (2a). Solid PTA (25 mg, 0.16 mmol) was added to a suspension of [Au(C≡CC₁₀H₇N₂)]_n (60 mg, 0.16 mmol) in CH₂Cl₂ (20 mL). After 45 min of stirring at room temperature, the resulting yellow solution was concentrated (10 mL), and *n*-hexane (10 mL) was added to precipitate a pale-yellow solid (77 mg, 90%). ³¹P NMR (161.9 MHz, CDCl₃, ppm): −48.2. ¹H NMR (400 MHz, CDCl₃, ppm): 8.73 (d, $J = 5.0 \text{ Hz}$, 1H, H₉), 8.65 (dd, $J = 12.0 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 1H, H₆), 8.36 (dt, $J = 12.0 \text{ Hz}$, $J = 4.8 \text{ Hz}$, 1H, H₁₂), 8.29 (dd, $J = 8.4 \text{ Hz}$, $J = 2.5 \text{ Hz}$, 1H, H₃), 7.80 (m, $J = 8.0 \text{ Hz}$, $J = 1.6 \text{ Hz}$, 2H, H₄ + H₁₁), 7.27 (ddd, $J = 8.0 \text{ Hz}$, $J = 4.0 \text{ Hz}$, $J = 2.0 \text{ Hz}$, 1H, H₁₀), 4.60–4.48 (AB q, $J = 13.0 \text{ Hz}$, 6H, H_{19b}, NCH₂N), 4.30 (s, 6H, NCH₂P). IR (KBr, cm^{−1}): 3425 (C–H), 2104 (C≡C), 1640 (C=N). ESI-MS(+): m/z 534.111 ([M + H]⁺); calcd m/z 534.112, 556.092 ([M + Na]⁺); calcd m/z 556.094).

Synthesis of [Au(C≡CC₁₀H₇N₂)(DAPTA)] (2b). Solid DAPTA (36 mg, 0.16 mmol) was added to a suspension of [Au(C≡CC₁₀H₇N₂)]_n (60 mg, 0.16 mmol) in CH₂Cl₂ (20 mL). After 45 min of stirring at room temperature, the resulting yellow solution was concentrated (10

mL), and *n*-hexane (10 mL) was added to precipitate a pale-yellow solid (82 mg, 85%). ³¹P NMR (161.9 MHz, CDCl₃, ppm): −23.0. ¹H NMR (400 MHz, CDCl₃, ppm): 8.75 (dd, $J = 4.0 \text{ Hz}$, $J = 0.6 \text{ Hz}$, 1H, H₉), 8.66 (dd, $J = 8.0 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 1H, H₆), 8.37 (dt, $J = 12.0 \text{ Hz}$, $J = 0.8 \text{ Hz}$, 1H, H₁₂), 8.32 (dd, $J = 11.8 \text{ Hz}$, $J = 0.4 \text{ Hz}$, 1H, H₃), 7.82 (m, 2H, H₄ + H₁₁), 7.28 (ddd, $J = 12.0 \text{ Hz}$, $J = 7.2 \text{ Hz}$, $J = 0.6 \text{ Hz}$, 1H, H₁₀), 5.78 (d, $J = 20.0 \text{ Hz}$, 1H, H_{19a}, NCH₂N), 5.66 (dd, $J = 20.0 \text{ Hz}$, $J = 12.0 \text{ Hz}$, 1H, H_{23a}, NCH₂P), 4.94 (d, $J = 16.0 \text{ Hz}$, 1H, H_{21a}, NCH₂N), 4.70–4.64 (m, 2H, H_{17a}, NCH₂P, + H_{21b}, NCH₂N), 4.15 (dt, $J = 20.0 \text{ Hz}$, $J = 4.0 \text{ Hz}$, 1H, H_{17b}, NCH₂P), 4.06 (d, $J = 20.0 \text{ Hz}$, 1H, H_{19b}, NCH₂N), 3.87 (s, 2H, H₂₄, NCH₂P), 3.57 (dt, $J = 20.0 \text{ Hz}$, $J = 4.0 \text{ Hz}$, 1H, H_{23b}, NCH₂P), 2.17 (s, 6H, COCH₃). IR (KBr, cm^{−1}): 3425 (C–H), 2104 (C≡C), 1640 (C=N). ESI-MS(+): m/z 606.132 ([M + H]⁺); calcd m/z 606.133, 1233.233 ([2M + Na]⁺); calcd m/z 1233.241).

Computational Details. All quantum-level calculations were performed with the Amsterdam Density Functional (ADF) program³¹ using the dispersion-corrected density functional ZORA-BLYP-D3-(BJ).³² A previous benchmark study on noncovalent interactions showed that it is essential to incorporate the dispersion correction.³³ Geometry optimizations of monomers and dimers were obtained with the TZ2P basis set. Geometry optimizations of tetramers were obtained with the TZP basis set, and the bond energies were computed with the TZ2P basis set (single point with the optimized structures). The small frozen-core approximation was applied. Symmetry was applied and is denoted in Table 1 and in the Supporting Information (SI). Solvent effects in H₂O and DMSO were estimated using the conductor-like screening model (COSMO),³⁴ as implemented in the ADF program.^{35,36} According to work by Riley et al.,³⁷ the dispersion correction does not need to be modified for solvated systems. The bond energy ΔE_{bond} of the dimers and tetramers is defined by eqs 1 and 2, respectively:

$$\Delta E_{\text{bond}} = E_{\text{dimer}} - 2E_{\text{monomer}} \quad (1)$$

$$\Delta E_{\text{bond}} = E_{\text{tetramer}} - 4E_{\text{monomer}} \quad (2)$$

where E_{tetramer} is the energy of the optimized tetramer, E_{dimer} is the energy of the optimized dimer, and E_{monomer} is the energy of one of the four different optimized monomers used.

RESULTS AND DISCUSSION

Synthesis and Characterization. Complexes **1** and **2** were obtained by the same methodology as that previously described in the literature for $[\text{Au}(\text{C}\equiv\text{CC}_5\text{H}_4\text{N})(\text{PTA})]$ ⁸ and $[\text{Au}(\text{C}\equiv\text{CC}_5\text{H}_4\text{N})(\text{DAPTA})]$.⁹ A CH_2Cl_2 suspension of the previously synthesized $[\text{Au}(\text{C}\equiv\text{CC}_{15}\text{H}_{10}\text{N}_3)]_n$ (for **1a** and **1b**) or $[\text{Au}(\text{C}\equiv\text{CC}_{10}\text{H}_7\text{N}_2)]_n$ (for **2a** and **2b**) polymer was stirred with the phosphine PTA or DAPTA in a 1:1 ratio (Schemes 1 and 2). The reaction was maintained under stirring at room temperature for 45 min. Coordination of these phosphines (PTA and DAPTA) immediately gave yellow solutions that, after concentration and the addition of *n*-hexane, yielded the corresponding complexes quantitatively.

Characterization of complexes **1** and **2** by ^1H and ^{31}P NMR and IR spectroscopies and mass spectrometry verified the successful formation of these products. Mass spectrometry measurements were able to detect the corresponding molecular peaks of the protonated species in all cases (see the SI). ^1H NMR spectra of the complexes recorded in CDCl_3 show the characteristic protons of the terpyridine^{38–41} (**1a** and **1b**) and of the bipyridine^{20,42} (**2a** and **2b**), together with the

characteristic patterns of the phosphines PTA (**1a** and **2a**) or DAPTA (**1b** and **2b**)^{8–11} (see the SI). $^{31}\text{P}\{^1\text{H}\}$ NMR spectra carried out in CDCl_3 typically show one signal between -10 and -50 ppm, with a 50 ppm (for PTA derivatives) or a 30 ppm (for DAPTA derivatives) downfield shift in comparison with the free phosphines. The corresponding $\text{C}\equiv\text{C}$ and $\text{C}=\text{N}$ vibrations of the chromophoric units were also observed in the IR spectra in all cases.

Aggregation in Water and Water/DMSO Mixtures. As was previously found for neutral gold(I) alkynyl complexes,^{8–10} aged solutions of **1a**, **1b**, **2a**, and **2b** in H_2O give origin to the formation of luminescent fibers (Figure S9), apparently originating from the merging of smaller aggregates¹⁰ (see the SAXS and DLS discussion below). The fibers are not observed from DMSO and chloroform solutions in the same time scale.

In D_2O , terpyridyl and bipyridyl protons are not observed in ^1H NMR, even under highly diluted conditions (Figure 1), while the phosphine protons are clearly seen, even if they are slightly broader than those in CDCl_3 . The absence of the terpyridyl and bipyridyl proton signals is an expected result from aggregation because of the slower mobility of the aggregates. What is unexpected is that the phosphine protons are still detected in the aggregates because the restriction in mobility should apply to both parts of the molecule.

In order to obtain deeper knowledge of the self-assembling process at the molecular level, we performed a series of NMR spectroscopy studies in $\text{D}_2\text{O}/\text{DMSO}-d_6$ mixtures because the good miscibility of both solvents and the complete solubiliza-

(c) ^1H NMR spectra of 1 mM **2b** in different solvent conditions. The experiments were acquired at 500 MHz and 298 K, with a relaxation delay of 20 s. Below the peaks, the numbers in red are the normalized peak area values (integral).

Figure 3. Schematic representation of the possible aggregates observed in solution.

tion of the molecules in $\text{DMSO-}d_6$ (Figure S10), having behavior comparable to that previously observed in CDCl_3 . We must point out that the very large aggregates are invisible in conventional solution NMR experiments because of the large line broadening produced by the very efficient transverse relaxation in large molecular entities. The ^1H NMR spectrum of **2b** in pure $\text{DMSO-}d_6$ showed well-resolved signals, implying the major presence of discrete species (Figures 2c, black trace, and S9) suitably assigned by 2D $^1\text{H}-^{13}\text{C}$ HSQC and HMBC experiments (Figures S11 and S12). However, two sets of signals were clearly observed in a 63:37 proportion, suggesting the presence of two species in solution (with notation H and H' in Figure 2). The NOESY spectrum of this sample showed a cross-peak between the H'_6 signal and the methyl signal of the

acetyl of the DAPTA moiety, suggesting that the minor species should locate the bipyridyl and DAPTA moieties in relatively close proximity (Figure S13).

The DOSY experiment (Figures S14 and S15) rendered an apparent molecular size corresponding to a dimer structure for the two observed species (Table S2; hydrodynamic radii of 7.3 and 8.6 Å for the minor and major species, respectively). Accordingly, we assigned the minor species to the chain dimer and the major one to the stacked dimer (Figure 3). Very interestingly, the measured longitudinal and transverse relaxation times (Table S1) are unexpectedly long for discrete organic molecules in solution. Moreover, the magnetic relaxation of the signals from the bipyridyl moiety showed to be less efficient than the relaxation of the DAPTA moiety. This

could be due to some rigidity of the bipyridyl group, although no definitive conclusions could be drawn due to the implication of the DAPTA moiety in a cis/trans dynamic process of the corresponding tertiary amide groups. Actually, the molecular system is implicated in the different exchange processes that occurred at very different time scales, as observed by the EXSY peaks in the NOESY experiments (Figure S13).

Thus, the amide cis/trans isomerization of DAPTA is slow in the chemical shift NMR time scale and can be observed by exchange cross-peaks in the NOESY experiments at 250 ms. Additionally, the exchange between the two dimeric species (chain/stacked; Figure 3) is slow in both the NMR chemical shift and NOESY time scales (exchange slower than 0.5 s). The complexity of the systems is even higher when looking at the integrals of the ^1H NMR signals. The ^1H NMR spectrum acquired at quantitative conditions (with a relaxation delay of 20 s) showed that the intensities of the bipyridine signals are lower than the ones for DAPTA, once again suggesting that the bipyridyl ring is closely implicated in the self-assembling process. Besides, a comparison of the integrals of the observed NMR signals with that of an internal standard showed that about 10% of the molecule remains undetected in solution NMR, suggesting the presence of large aggregates even in pure DMSO- d_6 . The apparent lower motion of the bipyridyl rings is also observed in the negative NOE cross-peaks, which implies a longer apparent tumbling time of this part of the molecule.

To study the effect of H_2O on the self-assembly, we performed a titration of the sample initially prepared in DMSO- d_6 with increasing amounts of D_2O (Figure S16). The increase of the polarity of the medium produced changes in the bipyridyl proton signals, which is in agreement with the previously reported behavior.⁴³ All the signals broadened, and the protons corresponding to the two dimeric species started to approach their chemical shifts (without an apparent variation in the proportion of the species). This suggests that the presence of H_2O accelerates the exchange between the two dimeric species. The DOSY experiment at 20% D_2O in DMSO- d_6 showed the clear presence of two dimeric species with apparent sizes similar to that observed in pure DMSO (Table S2 and Figure S17). However, the ^1H NMR signals coalesce at a 1:1 DMSO- d_6 / D_2O mixture, in which a single set of signals was observed for the bipyridyl moiety (Figure 2c, red trace). The NOESY spectrum of this sample showed peaks that are compatible with the two dimeric structures, implying that a fast exchange must occur between the chain and stacked species in this solvent mixture (Figure S18). This is also supported by the negative sign of the NOESY peaks, implying an apparent larger size of the species in solution rendering transferred NOESY effects between the dimeric species and larger aggregates. The integrals of the protons in the 1D ^1H NMR spectrum suggested a higher proportion of invisible aggregates, while the DOSY experiments (Figure S19) rendered values compatible with the presence of dimeric species and in equilibrium with larger aggregates (hydrodynamic radii of 7.8 and 15.0 Å for different signals of the spectrum; Table S2). Moreover, acquisition of the ^1H NMR spectrum after longer preparation times showed a decrease in the intensity signals with time (Figure 2b), implying the slow formation of very large self-assemblies (6 days).

Finally, the ^1H NMR spectrum of a sample prepared in pure D_2O showed a further decrease in the intensity of the protons of DAPTA and the complete disappearance of the signals from the bipyridyl moiety (Figure 2c, blue trace). The NOESY spectrum of this sample (Figure S20) showed spin-diffusion

effects in agreement with the formation of very large aggregates in solution where the bipyridine would be less accessible to the solvent, leading to a large broadening up to undetectable signals. A faster dynamic and solvent exposure of the DAPTA fragments allowed the detection of their NMR signals. The same behavior was observed for complex 2a in pure DMSO- d_6 and a 1:1 DMSO- d_6 / D_2O mixture (Figures S21–S26).

^{31}P NMR experiments recorded in different DMSO- d_6 / D_2O proportions are in agreement with these data. A broad signal is observed in pure DMSO- d_6 , implying the existence of different conformations in slow equilibrium. Moreover, the increase of the amounts of D_2O shifts to a sharp and clearly defined downfield peak, as expected when the equilibrium between the chain and stacked conformations becomes faster in D_2O (Figures S27 and S28).

Considering all of these NMR results, a putative self-assembling mechanism for gold(I) complexes 2a and 2b is proposed in Figure 3.

The aggregation has a visible impact on the optical properties of the solutions in both the absorbed and emitted light. With an increase in the H_2O content, there is a clear change of the absorption toward the visible region, displayed by the yellowing of the solutions, and at the same time, the strong blue emission observed in DMSO is quenched at increasing amounts of H_2O and replaced by a red emission (Figures 4 and S29).

Figure 4. (top) Variation of the color of 1×10^{-4} M D_2O /DMSO- d_6 solutions of 2b under visible and UV light. (bottom) Normalized emission of 2b at different compositions of DMSO- d_6 / D_2O ($\lambda_{\text{exc}} = 360$ nm).

The lower-energy band at ca. 630 nm is assigned to the aggregates, where the presence of excimers due to π - π or Au- π stacking can contribute to both the broad shape and red shift of the band.¹¹ These interactions seem to be more favored in H_2O , in agreement with theoretical calculations (see below). The higher emission band at 430 nm is assigned to the singlet metal-to-ligand charge-transfer ($^1\text{MLCT}$)/singlet ligand-to-

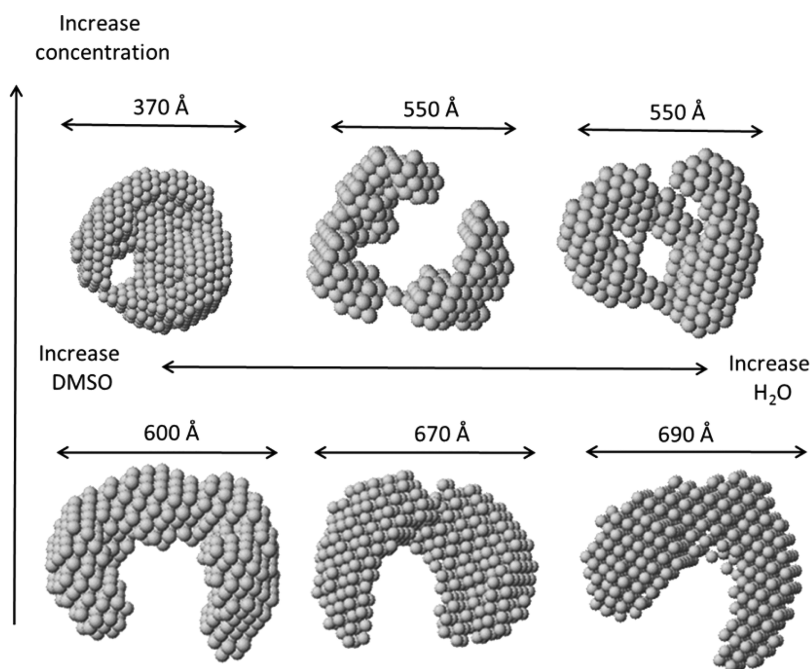

Figure 5. DAMMIN low-resolution structures reconstructed from SAXS patterns for 1×10^{-4} M (top) and 1×10^{-5} M (bottom) solutions of **2a** in DMSO (left), 1:1 H₂O/DMSO (center), and 3:1 H₂O/DMSO (right).

Figure 6. Structures of the computed dimers.

ligand charge-transfer (¹LLCT) transition, being more favored in DMSO, because of the presence of a chain conformation, which allows free movement of the phosphane and polypyridine moieties of the compounds in the aggregates (mainly aurophilic interactions).

SAXS measurements were performed for 1×10^{-5} and 1×10^{-4} M solutions of the compounds in different H₂O/DMSO proportions. The low-resolution structures were reconstructed ab initio from the scattering patterns using the DAMMIN program³⁰ and are shown in Figures 5 and S30–S32 for two concentrations and two solvent compositions.

The observation is that, in all mixtures, the large aggregates show comparable dimensions at the same concentration, independent of the solvent composition and, in general, a slight increase in the sizes of the aggregates is shown with an

increase in the H₂O concentration. There is no significant difference in the sizes between the terpyridyl and bipyridyl derivatives (Figures 5 and S30–S32). This result suggests that aggregates exist in the different H₂O/DMSO mixtures of the solvents, and the differences observed may arise from internal reordering of the aggregates (chain/stacked aggregates detected by NMR and luminescence). Additionally, the temperature does not significantly affect the size or the shape of the resulting structures (Figures S33–S36).

DLS measurements were in agreement with the presence of aggregates in DMSO at 1×10^{-4} M concentration. The presence of ca. 100 nm size supramolecular structures is observed in all cases (Figures S37–S40). As expected, the sizes of the aggregates obtained by DLS and SAXS are much larger than the hydrodynamic radii previously calculated by NMR

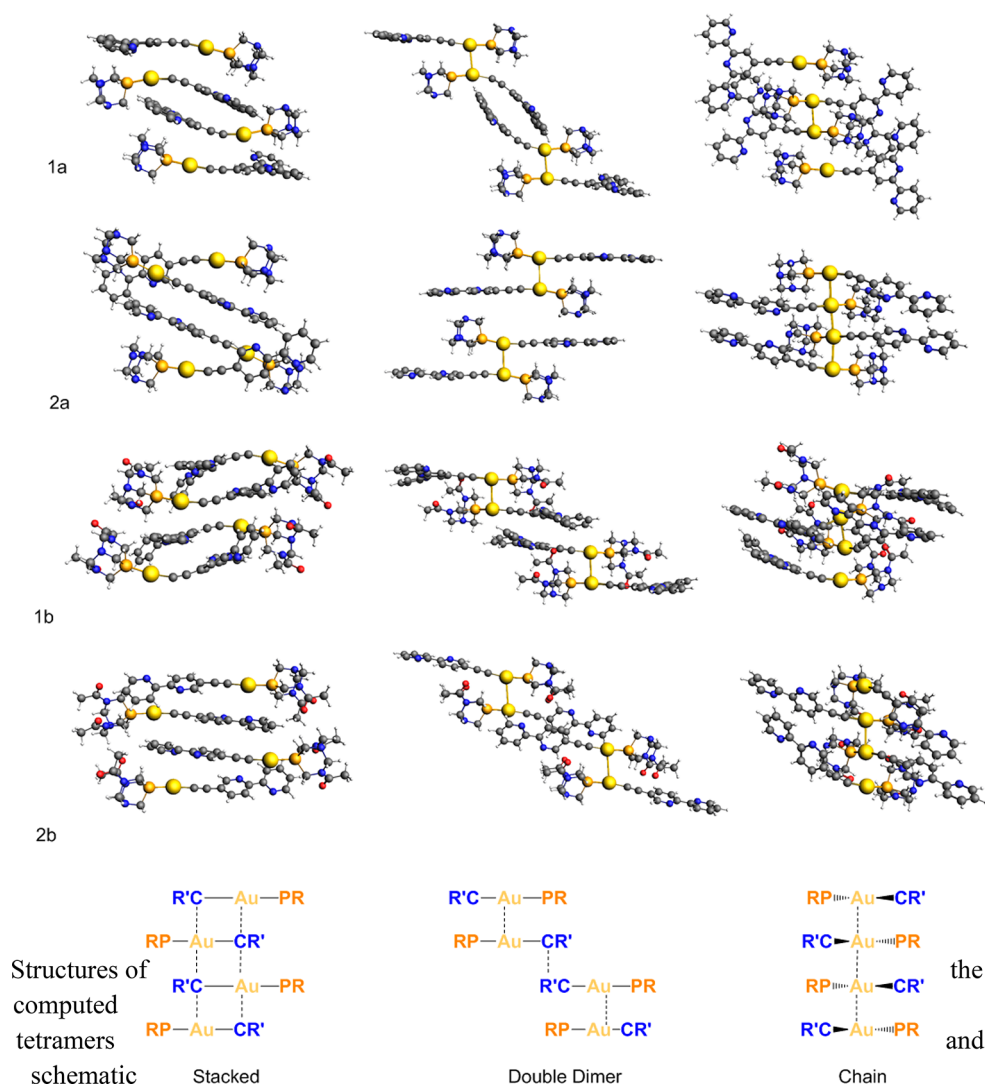

Figure 7.

DOSY experiments (see above). SAXS/DLS and NMR techniques are complementary toward the detected assembly size: because of the slow tumbling of larger macromolecules in solution leading to faster relaxation of transverse magnetization, only the soluble dimers and small aggregates in equilibria with the larger assemblies (detected by SAXS/DLS) are observed by NMR (the larger structures are “invisible” in solution NMR).

Computational Study of the Aggregation Modes. We have computationally analyzed the structures of **1a**, **1b**, **2a**, and **2b** (Figure S41) and their autoassociation properties to form different dimers and tetramers (as a model for larger aggregates).

We have analyzed different dimerization and tetramerization possibilities for each of the monomers in Figure S41, involving different arrangements of ligand–ligand, Au–Au, and ligand–Au interactions (Figures 6 and 7).

An important difference between the tetramers calculated is that, in the stacked conformation, the main contribution arises from Au– π interactions, in the double dimer, there are contributions from Au–Au and π – π interactions, while in the chain conformation, the main contribution is a continuous chain of Au–Au interactions that grows with the aggregate size.

The Au–Au distances between successive monomeric units in the tetramers and the bond energies are summarized in Table 1.

Note that, with no exception, there is a nonnegligible stabilization of the chain conformation in the tetramers. The same is not observed for the bond energies of the dimers, collected in Table 2. For the dimers, the conformations with shorter Au–Au distances (dimers 2 and 4, Au \cdots Au interactions) are not more stable than the conformations with favored ligand–ligand interactions, either in head-to-tail (dimer 1; $\pi\cdots$ Au interaction) or head-to-head (dimer 3; π – π interaction) conformations (Figure 6). That is, the formation of the dimers in H₂O in the stacked conformation is more favored according to these calculations (in agreement with the luminescence data), while the predicted stability of the larger structures does not seem to be so straightforward because entropic factors (not considered here) should be more important in the presence of $\pi\cdots$ Au interactions.

Another distinct aspect of the aggregation modes is related to the impact of the aggregates on the observables from either NMR, SAXS, and optical spectroscopies. For all of the tetramers, the favored aggregation modes are either stacked or chain aggregation. On the contrary, while chain aggregation minimizes hydrophobic interactions of the chromophoric unit

Table 2. Au–Au Distances (Å) and Bond Energies^a (kcal/mol) of the Tetramers of 1a, 1b, 2a, and 2b in H₂O

and maximizes exposure to the solvent, the stack aggregation maximizes the hydrophobic Au $\cdots\pi$ interaction, pulling the chromophoric unit toward the core of the aggregate while allowing the phosphine unit full exposure to the solvent. The stack aggregation thus is compatible with the excitonic interaction displayed in both the absorbed (yellowing) and emitted (quenching and red shift) light and can be the major species observed with an increase in the amount of D₂O in luminescence studies. By the same argument, chain aggregation is more compatible with the optical spectroscopy data obtained in DMSO, where both aromatic and phosphine protons are exposed to the solvent and the chromophore absorption in the UV, together with the blue emission, is recovered. At the same time, a second species (chain conformers) is detected in ¹H NMR spectra recorded in pure DMSO-*d*₆. Calculations performed in DMSO support this fact (Table S3). It can be seen that the contribution of the chain conformation becomes more important in this solvent, mainly in the bipyridyl complexes. In fact, the charge-transfer (CT) contribution observed in the case of the Au \cdots Au interactions⁴⁴ increases with the number of Au atoms involved in the chain and while a single Au \cdots Au bond is on the same order of magnitude as other interactions (Au $\cdots\pi$ and $\pi\cdots\pi$ stacking). With growth of the

number of Au atoms, these interactions become more important in stabilization of the aggregates.

We cannot forget that theoretical calculations take into consideration the bonding energy, while some entropic aspects, like hydrophobic interactions (expected to be more important for terpyridyl complexes), have a direct impact on the aggregation.

Reversible Aggregation/Dissaggregation Processes.

The presence of N-donor atoms in the chemical structure of the complexes makes these systems ideal candidates for cation coordination. The main important point in this work is that the coordination of cations may have a direct influence on the resulting aggregates being able to externally modulate the formation/dissolution of the supramolecular structures. The initial solutions display the typical π - π^* (C \equiv CC₁₅H₁₀N₃; for 1a and 1b) or π - π^* (C \equiv CC₁₀H₇N₂; for 2a and 2b) absorption transitions of chromophores between 310 and 360 nm.^{20,45,46} Additionally, a band at higher energy (ca. 280 nm) due to the intraligand absorption of the phosphine is also recorded, and another band at lower energy and with very low intensity between 360 and 400 nm is also present, which is assigned to a $\sigma^*_{\text{Au-Au}} \rightarrow \pi^*$ transition, in agreement with previous data based on theoretical and thermodynamic calculations^{44,47} (Figure S42). In order to check the ability of the complexes to coordinate metal cations, aqueous solutions (1 \times 10⁻⁴ M) of 1a–b, 2a–b were titrated with Zn²⁺, chosen as a divalent ion that can coordinate to N atoms. Absorption and emission variations in the presence of increasing amounts of Zn²⁺ were detected, and they are displayed in Figures 8 and S43–S45.

An interesting feature is observed with an increase in the amount of Zn²⁺. The broad intraligand absorption band turns to some vibronic resolution profile with higher absorption. Meanwhile, the red emission band disappears, and a blue fluorescence, previously assigned to ¹MLCT, rises for DMSO solutions. Emission bands resulting from Zn²⁺ coordination present some vibronic resolution, typical of nonaggregated chromophores. Additionally, the resulting blue emission is much higher in intensity than the red aggregated emission, as observed in the H₂O/DMSO solutions of the compounds.

The plot of the emission variations against the Zn²⁺ concentration displays a change in the slope at ca. 0.3 equiv (Figure 8, right inset), which is an indication of 1:3 (divalent cation/gold complex) coordination (Figure S46).

Figure 8. Absorption (left) and emission (right) spectra of a 1 \times 10⁻⁴ M aqueous solution of 2a in the presence of increasing amounts of Zn²⁺.

Figure 9. ^1H NMR spectra of 0.9 mM **2b** in D_2O and with increasing amounts of metal (1, 2, or 3 equiv of ZnCl_2) and after the addition of 6 equiv of cryptand to the sample with 3 equiv of Zn^{2+} .

Figure 10. DAMMIN low-resolution structures reconstructed from SAXS patterns for 1×10^{-4} M of **2a** (left) in H_2O , in the presence of 1 equiv of Zn^{2+} (middle), and in the presence of 1 equiv of Zn^{2+} and cryptand (right).

Interestingly, the red emission band appears again when a Zn^{2+} encapsulating agent (1,2-[bis(3-aminopropyl)amine]-ethane or 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]-hexacosane cryptand) is added to the solution (Figure S47), as a result of Zn^{2+} entrapment. This means that the aggregation state can be directly modulated, being an effective example of adaptive supramolecular systems modulated by external stimuli.

As mentioned before, the intensity reduction of bipyridine resonances for pure **2b** in D_2O are related to the longer rotational correlation times (τ_c) and shorter T_2 associated with the assembly process. Therefore, this assembly/disassembly process could be followed by monitoring the intensity changes on the NMR spectra. The addition of Zn^{2+} to a solution of **2b** in D_2O produced the intensity recovery of the ^1H NMR signals of the bipyridyl moiety. The observed chemical shifts of this fragment are in agreement with coordination of the Zn^{2+} ion to the bipyridine ring in a syn disposition of the N atoms.⁴⁸ The complexation of Zn^{2+} cations with an excess of complexing agent cryptand partially reverted the disassembly effects of Zn^{2+} , as observed by the concomitant decrease of the intensity of the aromatic signals in the upper spectrum of Figure 9. The presence of an excess of Zn^{2+} also shifted the DAPTA proton signals, suggesting a marginal interaction with the tertiary N atoms or the amide carbonyls of DAPTA (Figure 9).

SAXS experiments performed in the presence of Zn^{2+} followed by the addition of an encapsulating agent show that the enclosed structures of gold(I) complexes in H_2O (Figure 10, left) are disturbed in the presence of the divalent cation (Figure 10, middle), giving rise to smaller structures and going back to aggregation when the encapsulating agent traps the cation and allows the gold(I) complex to self-assemble again (Figures 10, right, and S48–S50).

These processes were observed also for samples in solution under optical microscopy. Well-organized fibrillar aggregates can be detected for an aqueous solution of complexes that disaggregate in the presence of Zn^{2+} and come back to aggregation when an encapsulating agent is added to the solution (Figure S51).

All in all, we have demonstrated for the first time the self-aggregation of discrete gold(I) complexes in H_2O that can be externally modulated by the presence/absence of a divalent cation. This process is reversible and has been detected by complementary techniques: NMR, absorption, emission, SAXS, DLS, and optical microscopy in solution.

CONCLUSIONS

Gold(I) alkynyl complexes containing bipyridine and terpyridine π systems and water-soluble phosphines (PTA and DAPTA) self-assemble in H_2O and DMSO, as shown by SAXS,

NMR, and DLS, with very distinct luminescence displayed in both solvents.

An exhaustive ^1H NMR study performed with different $\text{D}_2\text{O}/\text{DMSO}$ mixtures indicates the presence of two different assembly modes in the aggregates: chain assemblies, which are based mainly on aurophilic interactions, and stacked assemblies, which are based on $\text{Au}\cdots\pi$ interactions, which are confirmed by density functional theory calculations carried out in both solvents. The initial aggregates of nanometer size merge with time to the formation of fibers. This process is promoted by the presence of H_2O .

Bipyridine and terpyridine groups can complex metal cations, leading to the disassembly of aggregates in the presence of Zn^{2+} . This process can be reverted by the addition of complexing agents that sequester Zn^{2+} .

The supramolecular assemblies respond to the metal-ion content by significant changes in both the morphology and luminescence. On a speculative note, the system can constitute the basis of a supramolecular adaptative system toward the presence of metal cations and biological macromolecules able to compete for metal complexation in cells.
