Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

Theoretical Design and Calculation of a Crown Ether Phase-Transfer Catalyst Scaffold for Nucleophilic Fluorination Merging two Catalytic Concepts

Hydroxylated crown ether phase-transfer catalyst

Abstract

Fluorinated organic molecules are playing an increased role in the area of pharmaceuticals and agrochemicals. This fact demands the development of efficient catalytic fluorination processes. In this paper, we have designed a new crown ether with four hydroxyl groups strategically positioned. The catalytic activity of this basic scaffold was investigated with high level of electronic structure theory, such as the ONIOM approach combining MP4 and MP2 methods. Based on the calculations, this new structure is able to solubilize potassium fluoride in toluene solution much more efficiently than 18-crown-6 (18C6). In addition, the strong interaction of the new catalyst with the S_N2 transition state leads to a very important catalytic effect, with a predicted free energy barrier of 23.3 kcal mol⁻¹ for potassium fluoride plus ethyl bromide reaction model. Comparing with experimental data and previous theoretical studies, this new catalyst is 10⁴ times more efficient than 18C6 for nucleophilic fluorination of alkyl halides. The catalysis is predicted to be selective, leading to 97% of fluorination and only 3% of elimination. Catalytic fluorination of aromatic ring has also been investigated and although the catalyst is less efficient in this case, our analysis has indicated further development of this strategy can lead to more efficient catalysis.

Keywords: nucleophilic fluorination, phase-transfer catalyst, crown ether, nucleophilic substitution, nucleophilic aromatic substitution, organofluorine compounds

Introduction

The incorporation of a fluorine atom into organic molecules alters their properties such as pKa, lipophilicity and conformational structure. In fact, the presence of fluorine in biologically active molecules often leads to higher metabolic stability, efficiency and bioavailability.¹⁻⁷ These effects are attributed partly to the electronegativity of this element and its small radius.⁸⁻¹³ As a consequence of these unique effects, at least one fluorine atom is present in about 20% of pharmaceuticals and 30-40% of agrochemicals.^{2,14,15} Many of these compounds are fluorinated aromatics. Moreover, the radiolabeling of some molecules with ¹⁸F enables the use these compounds in positron emission tomography (PET), a helpful technique in early diagnosis of the various illness, such as Parkinson's and Alzheimer's disease.^{9,16,17} For the cited reasons, the organic fluorine chemistry is one of the most exciting areas of current research in chemistry.¹⁸⁻³¹

Nucleophilic substitution reactions are widely used routes for obtaining organofluorine compounds. Among the available nucleophilic methodologies for fluorination of aromatics, the diazotization with BF₄⁻ (Balz–Schiemann reaction)³² or with HF/pyridine are the most relevant routes for obtaining fluorinated aromatic compounds at large scale. However, these methods have the drawback of using hazardous and toxic reagents. Other important methodology is the halogen exchange or Halex reaction. This method requires the activation of the halogen atom by other moieties on the ring such as nitro groups or elevated temperatures. Furthermore, there is a predominance of by-products in the reaction mixture. Although usually considered unreactive towards nucleophilic attack, gas phase experimental studies have shown that aromatic rings are intrinsically highly reactive for nucleophilic substitution even for unactivated aromatics. In fact, theoretical calculations have indicated that the low reactivity found in liquid phase reactions is due to the substantial solvent effect.

Fluorinating reagents commonly utilized in nucleophilic fluorination via S_N2 or S_NAr reactions include alkali-metal fluorides and tetraalkylammonium fluorides. Alkalimetal fluorides have low solubility in dipolar aprotic solvents and the use of common protic solvents leads to low reactivity. The tetrabutylammonium fluoride (TBAF) salts are hygroscopic and only in the past decade has been obtained in anhydrous form. 35,36 Although useful in aromatic fluorination, TBAF acts as strong base, which can cause

elimination reactions in aliphatic compounds, leading in general to poor chemoselectivity.^{17,37} In addition, anhydrous TBAF are difficult to employ. Tetramethylammonium fluoride (TMAF) is a similar reactant and has been recently proposed to be a better alternative in aromatic nucleophilic substitution.³⁸

Despite the importance of fluorine in organic chemistry and the meaningful advances undertaken,³⁷ to introduce selectively and efficiently this element into poorly activated compounds remains an ongoing problem in fluorine chemistry.^{9,17} For example, although the successful use of selectfluor in many fluorination reactions, electrophilic fluorination of aromatics using selectfluor or other F⁺ source requires activated aromatics.^{18,39} Thus, there is a high demand for new methods to synthesize fluorinated compounds in a quick and selective procedure. Catalytic methods based on transition metals have received increased attention recently due important advances in this area.^{2,40,45} Other possibility is controlling the reactivity of the fluoride ion by designing supramolecular catalyst or structured nanoenvironment around the ion.⁴⁶⁻⁵⁰ This approach has been explored in this paper through computational chemistry. Hereafter, we have discussed key studies and ideas that had led us to design the new catalyst scaffold proposed in this work. It is worthwhile to emphasize the increased role of theoretical methods in the design of new catalysts, with successful outcomes.⁵¹⁻⁵³

The role of H-bonding in S_N2 and E2 reactivity and selectivity

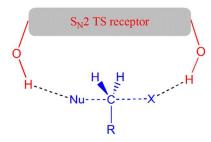

The fluoride ion is a small and highly reactive anion in the gas phase.^{33,54} In liquid phase, it is one of the most solvated single-charged anion. For example, its solvation free energy is –116.7 kcal mol⁻¹ in water and –109.2 kcal mol⁻¹ in methanol, which are two classical polar protic solvents.^{55,56} This high solvation leads to small reactivity, which can be enhanced in polar aprotic solvents like dimethyl sulfoxide and acetonitrile. In these cases, its solvation free energy becomes –96.1 and –88.4 kcal mol⁻¹, respectively. Considering that these four solvents have high dielectric constants, the difference in solvation and reactivity is owing to the solvation shell close to the ion. In other words, the hydrogen bonds involving the fluoride ion and the first solvation shell in protic solvents are critical for controlling its reactivity.^{47,57}

Almost thirty years ago, Landini *et al.* have reported that nucleophilic activity of hexyl₄N⁺F⁻(H₂O)_n in apolar solvents can be decreased by a factor of 10³ when *n* goes from zero to 8.5 water molecules.⁵⁸ In addition, they have observed the effect on basicity (E2 reaction) is even greater, decreasing the reaction rate by a factor of 10⁷ for six water molecules. Thus, although the reactivity is decreased for both S_N2 and E2 processes, the higher effect on the elimination favors the selectivity of the reaction toward the S_N2 process in the presence of hydrogen bonds. Posterior studies reported in 1998 have indicated that for secondary alkyl halides, the amount of alkenes produced is high, indicating that is need further developments for an efficient fluorination.⁵⁹

The effect of hydrogen bonding and steric hindrance on the fluoride reactivity was also investigated by Yonezawa and co-workers, 60 studying a series of hydrogenbonded TBAF complexes. For the S_N2 reaction of bromide benzyl with these complexes, they observed that the reaction rate was related directly to steric bulk and to number of groups able to form hydrogen bonding present in the alcohol complexed with TBAF (t-BuOH >> i-Pr-OH > n-BuOH $\sim n$ -Pr-OH > H₂O). More recently, Kim et al. ⁶¹-63 have investigated the reactivity of CsF directly in bulky alcohols solvents and showed that the selectivity of the S_N^2 process is enhanced in relation to E2. In addition, the TBAF(t-BuOH)₄ complex was isolated and characterized in 2008 by the same group. This complex is more selective for the nucleophilic fluorination and easier to handle than TBAF (hydrated or anhydrous).²⁰ Extending these studies, Gouverneur and coworkers have shown that the TBAF(t-BuOH)₄ complex is very efficient in Pd and Ircatalyzed fluorination of allylic p-nitrobenzoates and carbonates^{44,64}, while other fluoride sources are ineffective for these reactions. In 2015, the Gouverneur's group synthetized and characterized several fluoride-alcohol complexes varying from two to four alcohol molecules, depending on the steric hindrance and branching of each alcohol. The selectivity was up to four-fold S_N2 products in relation to the E2 products, although the reaction have become slower.⁴⁹

Although hydrogen bonding retards anion-molecule S_N2 reactions, the possibility of using hydrogen bonds to selectively stabilize the S_N2 transition state was hypothesized by Pliego in 2005 (Scheme 1).⁶⁵ Theoretical calculations have indicated that this stabilization is possible and could lead to higher reactivity and selectivity toward S_N2 process. The 1,4-benzenedimethanol (BDM) was theoretically investigated as a potential catalyst in nucleophilic fluorination.⁵⁷ However, the possibility of forming the $(F^-)_2(BDM)_2$ complex in DMSO solvent could eliminate any catalytic effect.⁴⁷ In

order to overcome this shortcoming, Pliego have proposed to use hydroxylated molecular cavities.⁴⁷ Theoretical calculations have indicated that a molecular cavity with four hydroxyls and a relative steric hindrance is effective for an excellent selectivity toward S_N2 reaction.⁴⁶ Thus, it was found that the NPTROL structure (Scheme 1) is able to complex with the reactants and to make the S_N2 transition state 5 kcal mol⁻¹ more stable than the E2 transition state. Additionally, the predicted free energy barrier for the S_N2 process in DMSO solvent has remained as low as 18 kcal mol⁻¹, indicating a rapid kinetics. These findings support the view that a molecular cavity with strategically positioned hydroxyl groups can selectively accelerate nucleophilic fluorinations using free fluoride ions.

Crown Ether Catalysis

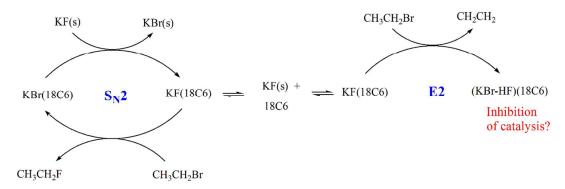

The use of KF as reagent in nucleophilic fluorination is very desirable since this salt is inexpensive and easily available. However, it requires a solid-liquid phase-transfer catalyst. With the discovery of crown ethers by Pedersen⁶⁶ in 1967, the potential use of crown ethers as phase-transfer catalyst has been explored. As early as 1974, Liotta and Harris⁶⁷ observed that 18C6 is able to catalyze the reaction of primary alkyl bromides with KF in benzene, leading to 92% of S_N2 product. However, the reaction has taken several days to complete in high temperature, which make it less useful.

The interest on crown ethers (and similar species) as catalysts in nucleophilic fluorination has resurged in past ten years. In 2007, Stuart and Vidal have investigated a new diaza-18-crown-6 derivative for fluorination of 2,4-dinitroclorobenzene and have found it is slightly superior to dibenzo-18-crown-6.⁶⁸ In 2009, Lee *et al.* have reported that tri and tetraethylene glycol are efficient solvents for nucleophilic fluorinations.⁶⁹ This property was attributed to the ability of these hydroxylated polyethers to interact with both the potassium cation and the fluoride ion, facilitating its solubilization and decreasing the fluoride basicity. Additional studies with penta and hexaethylene glycol has shown these species are even more efficient.⁷⁰ Furthermore, those authors have found that methylation on hydroxyl groups of pentaethylene glycol decreases the reactivity.

With the aim of understanding how crown ethers work at molecular level, Pliego and Riveros have recently reported a theoretical study of the model reaction between ethyl bromide and KF catalyzed by 18C6.⁷¹ The proposed mechanism is presented in Scheme 2. The initiation step is the dissolution of the KF by the 18C6 in apolar solvent. In the next step, which initiates the catalytic cycle, there is a nucleophilic attack of the complexed fluoride ion to the substrate (alkyl halide). The strong complexation of the crown ether with the potassium cation makes the fluoride anion highly reactive, and the calculated activation free energy barrier was as low as 14 kcal mol⁻¹. However, the next catalytic step is the exchange reaction between the solid KF and the KBr(18C6) complex, regenerating the KF(18C6) species. Unfortunately, this step requires 11 kcal mol⁻¹ and leads to a slow final kinetics. Other important result was the observation that

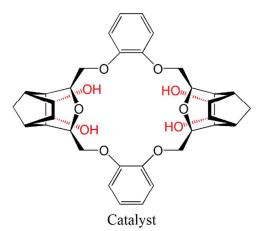

the crown ether makes the E2 mechanism less favorable and the main product is the alkyl fluoride.

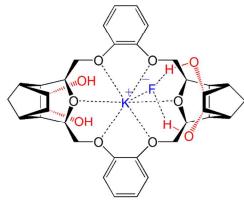

In the past year, the Kim group evaluated the reactivity of the KF(18C6) toward an alkyl mesylate.⁷² In this case, the reactivity they have found was much lower than that of bromide as leaving group. Considering the reaction taking place in benzene, they have observed only 13% conversion after 12 h at 100°C. This kinetics corresponds to a free energy barrier of 31 kcal mol⁻¹.

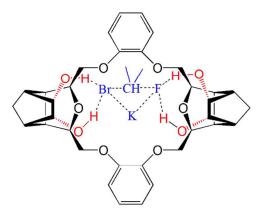

Scheme 2. Proposed catalytic cycles through S_N2 and E2 pathways. Solubilization of KF by 18C6, reaction between KF complexed with 18C6, KF(18C6), and the alkyl bromide and the regeneration of complex KF(18C6). In the E2 mechanism, the release of HF could inhibit the catalysis.

The idea of combining crown ether and hydroxyl groups was further explored by Kim and co-workers. An interesting example was the combination of 18C6 with calix[4]arene (BACCA), generating a species able to complex with CsF. The idea behind this approach is to complex the cesium ion with the crown ether moiety, while the fluoride ion complexes with two tert-alcohol groups of the BACCA molecule. In the view of those authors, the separation of Cs⁺ and F⁻ ions would promote the higher reactivity of the fluoride ion, even considering its interaction with hydroxyl groups. Thus, the fluorination of an alkyl mesylate in acetonitrile solvent and using KF has led to conversion of 42% in 24 h at 100°C. Based on these data, it can be estimated an activation free energy barrier of 30 kcal mol⁻¹.

Merging the Catalytic Concepts

The use of crown ether and hydrogen bonds have proved to be an useful approach for creating new molecules able to promote or catalyze nucleophilic fluorination. In particular, we think that hydroxyl groups should be placed in distant positions like shown in Scheme 1 to stabilize the transition state. In the case of crown ethers, the problem of exchange reaction in Scheme 2 points out that is need to stabilize the fluoride ion more than the bromide ion to favor this step. Because is known that the fluoride ion has stronger interaction with a water molecule than the chloride (and bromide), the introduction of hydroxyl groups in crown ether would favor this exchange. Therefore, it was designed the new hydroxylated crown ether presented in Scheme 3. The idea is that this structure would favor the exchange reaction and would stabilize the S_N2 transition state. Thus, this report presents a theoretical study the reaction between KF and CH₃CH₂Br in toluene, exploring the new designed molecule as a potential catalyst. Its structure, based on dibenzo-18-crown-6 and four hydrogen bonds strategically positioned, was named DB18C6-4OH. The use of reliable level of theory can provide important insights and predictions on this process and be useful in the development of this new class of catalysts.

Ab initio Calculations

The reaction of KF(DB18C6-4OH) with ethyl bromide was studied by electronic structure methods. Full geometry optimization and harmonic frequency calculations were carried out with the X3LYP⁷³ functional and 6-31(+)G(d) basis set. This basis corresponds to the 6-31G(d) basis set for C, H and K atoms and the 6-31+G(d) basis set for N, O, F and Br atoms. The choice of the X3LYP functional is based on its good performance for obtaining geometries and describing hydrogen bonds. In addition, it has better performance than the widely used B3LYP functional.^{74,75} The solvent effect (toluene) was included by means of integral equation formalism polarizable continuum model (IEF-PCM)⁷⁶⁻⁷⁹ and the SMD method⁸⁰ that includes nonelectrostatic solvation contribution. In this case, we have used the X3LYP/6-31(+)G(d) electronic density.

To obtain reliable electronic energies, it was performed single point energy calculations with the ONIOM method.⁸¹ This is a composed approach and a part of the system, named model system, is described by higher level of theory, while the whole system is treated by lower level. The energy of the ONIOM method is obtained through equation 1:

$$E_{ONIOM} = E_{real\,system}^{lower\,level} + (E_{model\,system}^{higher\,level} - E_{model\,system}^{lower\,level}) \tag{1}$$

In the present study, the model system is the species KF + CH₃CH₂Br and the real system has included the catalyst. It was used the MP4 method for the model system and the MP2 method for the complete system, both of these calculations using the Ahlrichs's def2-TZVPP basis set⁸² extended with sp diffuse functions on F, Cl, N, O and Br with exponents 0.07, 0.05, 0.05, 0.06 and (0.055(s)/0.033(p)), respectively. These basis sets are similar to the minimally augmented Karlsruhe basis sets of Truhlar and co-workers.⁸³ Therefore, our calculations corresponds to ONIOM (MP4/TZVPP+diff: MP2/TZVPP+diff) level.

Other system investigated was the S_NAr reaction between the KF(DB18C6-4OH) complex and p-bromobenzonitrile in toluene solution. The level of theory was the same used for the S_N2 reaction.

The free energy for reaction and activation steps was calculated by equations 2 and 3:

$$\Delta G_q^* = \Delta E_{elet} + \Delta G_{vrt}^* \tag{2}$$

$$\Delta G_{sol}^* = \Delta G_g^* + \Delta \Delta G_{solv}^* \tag{3}$$

where ΔE_{elet} is the electronic energy contribution, ΔG_{vrt}^* is vibrational, rotational and translational contributions obtained through calculations of harmonic vibrational frequencies. The sum of these terms leads to the gas phase free energy contribution. The $\Delta\Delta G_{solv}^*$ term was obtained from the calculation of the solvation free energy using the SMD solvation model. For all of these processes, the standard state of 1 mol L⁻¹ was used for both gas and solution phases as indicated by symbol *. All the calculations were carried out with GAMESS⁸⁴ and FIREFLY⁸⁵ programs.

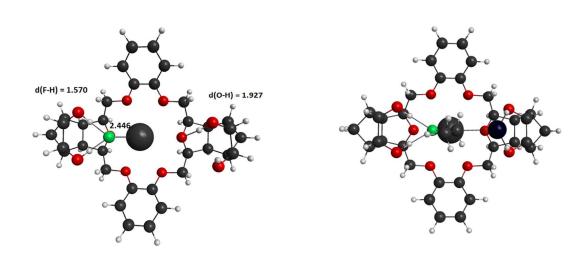

Results and Discussion

Stability of the KF(DB18C6-4OH) and KBr(DB18C6-4OH) complexes

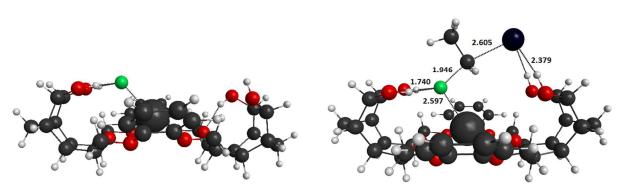

An important step in the solid-liquid phase-transfer catalysis is the solubilization of the salt via formation of the KF(catalyst) complex. The structure of this complex, named KF(D18C6-4OH), is presented in Figure 1 and it can be seen that the fluoride ion interacts with both the potassium ion and the two hydroxyl groups. The bond length between the fluoride ion and the hydroxyl hydrogen is 1.57 Å, suggesting a very strong interaction. The thermodynamics data is presented in Table 1. The interaction energy of the KF with DB18C6-4OH is 56.2 kcal mol⁻¹, while the interaction with 18C6 is only 42.3 kcal mol⁻¹. Considering the solid KF, we have combined experimental thermodynamics data with theoretical values to estimate the standard free energy for solubilization of KF in toluene using DB18C6-4OH (process 11, table 1). It was calculated a value of 1.6 kcal mol⁻¹ for this process using processes (3), (5) and (6), indicating an enhanced ability of the new crown ether to solubilize the KF salt. For comparison, in the case of 18C6, this free energy is 15.3 kcal mol⁻¹ (using processes (1), (5) and (6) to obtain the process (9)). This high value points out that the new catalyst scaffold is much more efficient than 18C6 one for solubilizing KF. The same analysis was performed for KBr. In this case, the bond length between the Br atom and the hydroxyl hydrogen is 2.33 Å. The free energy for solubilization of KBr (calculated using processes (2), (7), and (8) for obtaining the process (10) and applying processes (4), (7) and (8) for obtaining the process (12)) is 1.2 and 3.8 kcal mol⁻¹ with DB18C6-4OH and 18C6 in toluene, respectively. These results show the higher affinity of the new catalyst with KF and a small effect for KBr if compared to 18C6. Such property is very important to the efficiency of the catalyst, because facilitates the solubilization of KF, while the KBr generated in the process does not inhibit the reaction.

In the above analysis, it can be observed a point not taken in consideration in our previous study on crown ether catalysis.⁷¹ The free energy for solubilization of KBr by 18C6 is positive by 3.8 kcal mol⁻¹, meaning that the KBr released in the reaction forms solid KBr and free 18C6. As a consequence, the exchange reaction in Scheme 2 does not contribute to the overall barrier. Rather, the solubilization of solid KF by the 18C6

is a critical step. This fact increases the overall activation free energy barrier and makes our predicted value closer to the experimental one. This point will be discussed ahead along with the reaction free energy profile (Figure 2).

The S_N2 and E2 Reactions of KF(DB18C6-4OH) with CH₃CH₂Br

The reaction between KF complexed with DB18C6-4OH and ethyl bromide was studied in toluene solution. This analysis can provide the effect of the new crown ether catalyst on the reactivity and selectivity. The reaction pathways are presented in Scheme 4. The fluorination takes place through the S_N2 mechanism, while the E2 process occurs via both syn and anti transition states. The optimized structures are presented in Figure 1. We can notice the TS1-cat structure corresponds to the S_N2 transition state interacting with the DB18C6-4OH catalyst and supports our conceptual view of the mode of action envisioned in Scheme 3. The activation free energy barrier is 21.7 kcal mol⁻¹. Considering that the solubilization free energy is only 1.6 kcal mol⁻¹, the final barrier becomes 23.3 kcal mol⁻¹, indicating that the DB18C6-4OH catalyst is able to promote efficiently nucleophilic fluorination.

The other two pathways via E2-anti and E2-syn are also able to interact with the new crow ether. However, the respective barriers involving the solubilized KF(DB18C6-4OH) are 25.5 and 28.5 kcal mol⁻¹. The difference of 2.2 kcal mol⁻¹ for E2 anti in relation to the S_N2 mechanism indicates an important selectivity towards nucleophilic fluorination, which should correspond to 97% of the products. Similar to 18C6, the formation of HF in the E2 pathway leads to a stable (KBr-HF)(DB18C6-4OH) complex, which probably inhibits the catalysis.

b – Data relative to the CH₃CH₂Br + KF(DB18C6-4OH) reactants in toluene solution.

c – Taken from reference ⁷¹.

The data presented in Table 1 allows us to build a free energy profile of the reaction. For a better appreciation of the catalytic property of the new molecule, it was included the free energy data for the reaction of free KF with ethyl bromide and the effect of the 18C6 catalyst reported in a previous study. The free energy profile for these three processes are presented in Figure 2. In the analysis of the reaction of free KF in toluene, the solubilization of this species require 40.7 kcal mol⁻¹ and its reaction through the S_N2 mechanism requires more 24.3 kcal mol⁻¹, the leading to a final barrier of 65 kcal mol⁻¹. This is a very high barrier and no reaction by this pathway will be observed. In fact, it is possible that the reaction of CH₃CH₂Br with the solid KF, taking place on its surface, is more favorable.

The other process is the reaction catalyzed by 18C6. The solubilization of KF by 18C6 requires a free energy of 15.3 kcal mol⁻¹, which is 25.4 kcal mol⁻¹ lower than solubilization of free KF. The barrier for the S_N2 process is 14.0 kcal mol⁻¹ and adding these two steps, the final barrier becomes 29.3 kcal mol⁻¹. The KBr(18C6) complex is 3.8 kcal mol⁻¹ above of the KBr(s) + 18C6 products. Therefore, following the catalytic cycle of Scheme 2, the KBr(18C6) species formed leads to KF(18C6), which releases the 18C6 catalyst and initiates the process again. At 25°C, the calculated free energy of activation is 29.3 kcal mol⁻¹, while the experimental value was estimated as 30.3 kcal mol⁻¹ at 90°C. This excellent agreement is an important support for the mechanism proposed in this work. In addition, we can notice the catalytic effect is very high, decreasing the overall barrier by 35.7 kcal mol⁻¹!

The new catalyst designed in this work overcomes an important limitation of the 18C6 species: the solubilization of the KF. The free energy for this process is only 1.6 kcal mol⁻¹, indicating that the interaction of the fluoride ion with the two hydrogen bonds is very effective. In the activation step, the reaction of ethyl bromide with the KF(DB18C6-OH4) has a barrier of 21.7 kcal mol⁻¹. The sum of these two steps leads to the overall barrier of only 23.3 kcal mol⁻¹. Comparing with the 18C6, the barrier decreases by 6 kcal mol⁻¹, amounting to a rate acceleration effect of 10⁴! This very meaningful catalytic effect should make this catalyzed process very effective and useful. For a more quantitative evaluation, we can write a kinetic model. Based on the free energy profile, the reaction rate is given by equation 4:

$$\frac{d[EtBr]}{dt} = -k_2 K_{sol} C_{cat} [EtBr] \tag{4}$$

where k_2 (7.7 x 10^{-4} L mol⁻¹ s⁻¹, at 25° C) it is the solution phase bimolecular reaction rate constant, K_{sol} (0.067, 25 °C)) is the solubilization equilibrium constant and C_{cat} the catalyst concentration. Considering the last value is 0,10 mol L⁻¹, the pseudo first-order rate constant becomes 5.2 x 10^{-6} s⁻¹. Using the same free energy values at 70 °C, it can estimated that 98% of the reaction takes place within 1 hour. If these data are correct, the DB18C6-4OH is the most efficient phase-transfer catalyst designed for nucleophilic fluorination to date. For comparison, two previous reports^{72,48} have presented catalysts with activation barriers around 30 kcal mol⁻¹. In the case of the new catalyst investigated in this article, the barrier is predicted to be only 23.3 kcal mol⁻¹. In addition, many prior studies require CsF as substrate, while the present catalyst is able to work with KF. In our view, this difference is due to the strategically positioned hydroxyl groups, which interact with the center of negative charge of the transition state. Thus, the combination of hydrogen bond with the crown ether seems to be a very effective strategy for fluorination of alkyl halides.

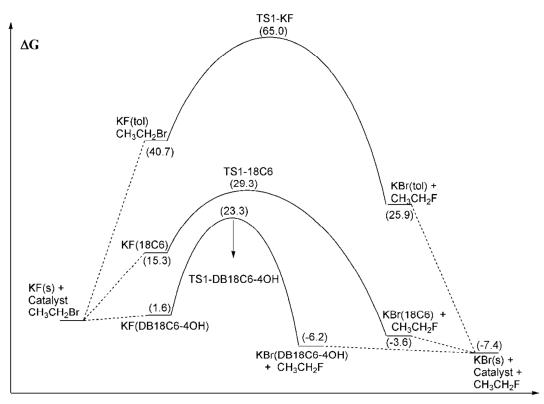

Figure 2: Free energy profile for S_N2 reaction of KF(s) with ethyl bromide in toluene solution involving solubilized potassium fluoride (KF(tol)), KF complexed with 18-crown-6 and KF complexed with DB18C6-4OH. (Values for activation and reaction of KF(s) + CH₃CH₂Br and KF(18C6) + CH₃CH₂Br processes were taken from the reference 70).

The S_NAr reaction of KF(DB18C6-4OH) with *p*-bromobenzonitrile

It is worthwhile to analyze the possibility of the new catalyst to be active for aromatic fluorination. Thus, it was also studied the catalytic effect of DB18C6-4OH for aromatic nucleophilic substitution (S_NAr) reactions. The studied reaction is the fluorination of p-bromobenzonitrile as indicated in Scheme 5 below. It was evaluated the reaction with and without the catalyst. The results are in Table 2 and Figure 3.

Scheme 5: The S_NAr reaction investigated in this work.

The transition state related to the reaction of the potassium fluoride in toluene, KF(tol), (without catalyst) has a free energy barrier of 22.8 kcal mol⁻¹, which can be compared with the barrier of 24.3 kcal mol⁻¹ for the previously investigated S_N2 process. Nevertheless, the free energy of 40.7 kcal mol⁻¹ for solubilization of the KF(s) makes this pathway unviable.

In the case of catalyzed S_N Ar process, represented by scheme 5, the free energy barrier involving the soluble complex is 25.2 kcal mol⁻¹, whereas the S_N 2 reaction has a barrier of 21.7 kcal mol⁻¹. Adding the 1.6 kcal mol⁻¹ for solubilization of KF(s) through complexation with DB18C6-OH4, the final barrier for the S_N Ar process becomes 26.8 kcal mol⁻¹. Considering the reaction takes place at 90°C and that the free energy barrier does not change with the temperature, it can be estimated a time of 24 h for 99% of conversion. Looking at the both transition states, it can be noticed more efficient hydrogen bond between the catalyst and the S_N 2 transition state than for the S_N Ar one. In fact, the more compact S_N Ar transition state would beneficiate from less distant hydroxyl groups.

For comparison, Sanford and co-workers³⁸ have investigated the reactivity of tetramethylammonium fluoride (TMAF) in dimethylformamide solvent. They have reported that the reaction between 2-bromobenzonitrile with anhydrous TMAF provide 48% of product at 25°C, within 24 h. Considering a bimolecular kinetics, this translate to a free energy barrier of 24.3 kcal mol⁻¹, a few kcal mol⁻¹ below of our catalyzed barrier. A similar reaction was theoretically investigated by Pliego and Pilo-Veloso.³⁴ They have calculated a barrier of 26.3 kcal mol⁻¹ for S_NAr reaction of TMAF with *p*-chlorobenzonitrile in dimethyl sulfoxide solvent at 25°C. If the present calculations are accurate, the process simulated has an advantage over that with TMAF one, once it makes use of KF reagent and toluene solvent. Furthermore, it is evident that a more efficient catalyst can be designed for the S_NAr reaction. The new catalyst should have the hydroxyl groups in opposed positions closer each other to better stabilize the S_NAr transition state.

Table 2: Thermodynamics data for S_NAr reaction.^a

Processes	ΔΕ	ΔG^*_{g}	$\Delta\Delta G^*_{solv}$	ΔG^*_{sol}
p -bromobenzonitrile + KF(tol) \rightarrow	9.97	17.87	4.88	22.75

p -bromobenzonitrile + KF(tol) \rightarrow	-16.26	-15.75	2.20	-13.55
<i>p</i> -fluorobenzonitrile + KBr(tol)				
p-bromobenzonitrile + (KF)(DB18C6-4OH) → TS4-cat	12.41	22.57	2.64	25.21
p -bromobenzonitrile + (KF)(DB18C6-4OH) \rightarrow p -fluorobenzonitrile + (KBr)(DB18C6-4OH)	-8.61	-8.55	0.42	-8.13

a - Units in kcal mol^{-1} . Standard state of 1 $\text{mol}\ L^{-1}$ for both gas and solution phases. Geometry optimizations at X3LYP/6-31(+)G(d) level. Single point energies at ONIOM(MP4/TZVPP+diff: MP2/TZVPP+diff) level and solvent effect using the SMD method. b – TS4 is the transition state for the uncatalyzed reaction.

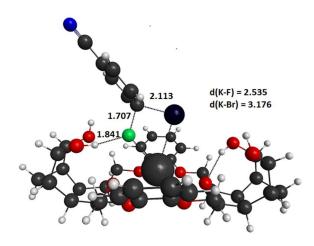

Figure 3. Structure of the TS4-DB18C6-4OH transition state related to the catalyzed S_N Ar reaction of KF(DB18C6-4OH) with *p*-bromobenzonitrile.

Conclusions

A new crown ether scaffold based on dibenzo-18-crown-6 with strategically positioned four hydroxyl groups has been designed and computationally evaluated for catalytic activity. Based on high level of theory, the proposed catalyst is much more efficient than 18-crown-6 ether for solubilizing KF in toluene solution. In addition, the strong interaction of the new catalyst with the S_N2 transition state for fluorination of ethyl bromide leads to a free energy barrier 6 kcal mol⁻¹ lower than that calculated for 18C6, resulting a reaction rate 10^4 times higher. The calculations have also indicated that the catalyst is selective towards the fluorination and the competitive E2 process is 2.2 kcal mol⁻¹ less favorable, resulting in 97% of selectivity for fluorination of a primary halide. The feasibility of the catalyst to be active for fluorination of aromatics via S_NAr process has also been investigated. In this case, the interaction of the catalyst with the S_NAr transition state is less effective, although the catalysis is also feasible. In summary, it was designed a new crown ether scaffold with very promise catalytic activity, which can be very useful in selective nucleophilic fluorination using the cheap, green and available KF as reagent.
