Supporting Information

**ABSTRACT:** The torquoselectivity of the  $4\pi$  electrocyclic ring-opening reaction of 2-azetines can be controlled by the Brønsted acidity of the catalyst and the polarity of the solvent. DFT calculations provided insight into the mechanism of this remarkable switch. Anti and syn stereoisomers of  $\alpha_{,\beta}$ -unsaturated amidines were selectively synthesized from ynamides and aldimines in the presence of Tf<sub>2</sub>NH and CSA, respectively.

 $4\pi$  Electrocyclic ring-opening reactions of cyclobutene analogues to give 1,3-dienyl compounds have attracted the attention of many synthetic and theoretical chemists.<sup>1</sup> The stereochemical process by which geometrical isomers are formed in these reactions is referred to as "torquoselectivity".<sup>1a</sup> The thermal conrotatory  $4\pi$  ring-opening allows two senses of rotation of the terminal substituents of the double bonds of the product (inward versus outward rotation). Both steric and electronic factors affect torquoselectivity (Figure 1). Using ab initio calculations, Houk and co-workers showed that electronic effects dominantly control the torquoselectively and an electron-donating substituent at the C-4 position tends to rotate outward, whereas an electron-accepting substituent rotates inward (mode a).<sup>1a</sup> This theoretical prediction successfully explains many experimental results.<sup>2</sup> Steric effects can influence on the torquoselectivity of the  $4\pi$  ring-opening when the electronic properties of the substituents are not significantly different. When the C-3 substituent is sterically smaller than the forming C(=X)R moiety, the bulky C-4 substituent tends to undergo an outward rotation (mode b). When the C-3 substituent is sterically bulky, an inward rotation of the larger C-4 substituent is preferred (mode c).<sup>3</sup> We have recently reported a selective synthesis of  $\alpha_{\beta}$ -unsaturated amidines bearing a TIPS group at the  $\alpha$ -position from ynesultams and aldimines by a domino [2 + 2] cycloaddition— $4\pi$ ring-opening in which the torquoselectivity was determined by the steric bulk of the C-3 substituent (mode c).<sup>3</sup>

In most reported cases of  $4\pi$  ring-opening, including our earlier effort, the torquoselectivity of the electrocyclic reaction is critically dependent on the properties of the substrates; a stereoselective synthesis of both geometrical isomers of the 1,3-dienyl compound from the same substrate is difficult.<sup>4</sup> We now disclose a catalystcontrolled synthesis of  $\alpha$ , $\beta$ -unsaturated amidines in which the rotation modes of the torquoselective electrocyclic ring-opening step can be switched by the properties of the acid catalysts.

**Figure 1.** Modes of torquoselectivity in the  $4\pi$  ring-opening reaction. Substituents, D, A, S, and L, signify electronically donating, electronically accepting, sterically small, and sterically large groups, respectively.

Scheme 1. Catalytic Reaction of Ynecarbamate 1 with Aldimine 2 Giving  $\alpha_{J}\beta$ -Unsaturated Amidine 3

During the course of our efforts to synthesize a variety of  $\alpha$ ,  $\beta$ -unsaturated amidines, we observed reverse stereoselectivity in the reaction of ynecarbamate 1<sup>4</sup> with aldimines 2 (Scheme 1). When the reaction of 1a (R<sup>1</sup> = Me, R<sup>2</sup> = TMS) with 2a (R<sup>3</sup> = R<sup>4</sup> = p-CF<sub>3</sub>C<sub>6</sub>H<sub>4</sub>) in toluene was carried out with triflic imide (Tf<sub>2</sub>NH) as a catalyst, a mixture of two geometrical isomers, *anti*- and *syn*-3aa, was obtained in 95% yield (*anti:syn* = 92:8) (Table 1, entry 1). Using triflic acid (TfOH) and anhydrous tetrafluoroboric acid as catalysts also gave 3aa in similar yields and selectivities (entries 2 and 3). Surprisingly, the stereoselectivity of 3aa was inverted (*anti:syn* =  $\sim$ 15: $\sim$ 85) when methane-sulfonic acid (MsOH) and 10-camphorsulfonic acid (CSA) were

employed as catalysts (entries 5 and 6). Using *p*-toluenesulfonic acid (TsOH) resulted in a low yield of **3aa** with low selectivity (entry 4). These results suggested that the acidity of the catalysts affected selectivity; strong Brønsted acids (the  $pK_a$  of TfOH in CH<sub>3</sub>CN is 2.6)<sup>5</sup> primarily produced the *anti*-product, whereas weaker acids (the  $pK_a$  of MsOH in CH<sub>3</sub>CN is 10)<sup>6</sup> selectively furnished the *syn*-adduct. We have confirmed that isomerization between *anti*- and *syn*-**3aa** does not occur under the reaction conditions.

It has been shown that the stereochemistry of **3** is kinetically determined during the conrotatory ring-opening of 2-azetine 4.<sup>7,8</sup> The possibility of acid-catalyzed *anti/syn* isomerization of **3** was ruled out; no isomerization of *anti-3aa* and *syn-3aa* was observed after 24 h in the presence of Tf<sub>2</sub>NH and CSA. As previously reported by Houk et al.,  $4\pi$  electrocyclic ring-opening of 2-azetines may proceed exothermically without the assistance of catalysts.<sup>7a</sup> However, our data clearly demonstrate that the torquoselectivity of **4** can be switched by the properties of the acid catalysts. To the best of our knowledge, these are the first observations of a significant influence on the torquoselectivity of the  $4\pi$  ring-opening reaction by a catalyst.<sup>9</sup>

To clarify the origins of catalyst-induced reverse torquoselectivity, the transition states for the  $4\pi$  electrocyclic ring-opening of the simplified model compound **4ab** (R<sup>1</sup> = Me, R<sup>2</sup> = TMS, R<sup>3</sup> = Ph, R<sup>4</sup> = *p*-CF<sub>3</sub>C<sub>6</sub>H<sub>4</sub>) were calculated using density functional theory (DFT) at the B3LYP/6-31(d) level.<sup>10</sup> The energy difference ( $\Delta G^{\circ}$ ) between the diastereomeric ammonium

<sup>*a*</sup> Conditions: **1a** ( $\mathbb{R}^1$  = Me,  $\mathbb{R}^2$  = TMS), **2a** ( $\mathbb{R}^3 = \mathbb{R}^4 = {}^{p}CF_3C_6H_4$ ) (1.2 equiv), catalyst (20 mol %), solvent (0.3 M), rt, 24 h. <sup>*b*</sup> Catalyst (10 mol %), 30 min. <sup>*c*</sup> Ratios were determined by <sup>1</sup>H NMR.

salts *cis*- and *trans*- $[4ab \cdot H]^+$  is small, and the diastereomers rapidly equilibrate via deprotonation, inversion of a nitrogen atom, and reprotonation under the reaction conditions. Following the Curtin—Hammett principle,<sup>11</sup> we considered four possible transition states: inward (**TSs A** and **B**) and outward (**TSs C** and **D**) rotations of the R<sup>3</sup> substituent and *cis* (**TSs A** and **C**) and *trans* (**TSs B** and **D**) relationships between the R<sup>4</sup> and R<sup>3</sup> substituents (Figure 2). The *E/Z* stereochemistry of the C=N moiety of **3** (oxazolidinone vs R<sup>4</sup>) readily epimerizes,<sup>12</sup> and the *E* geometry is much more stable than the *Z* geometry. Therefore, only the geometry of the C=C bond reports the torquoselectivity of the ring-opening reaction.

Table 2 summarizes the relative Gibbs free energy  $(\Delta\Delta G^{\dagger}$  of the **TSs A**-**D** under three sets of conditions: (1) in the presence of proton (a naked ammonium cation), (2) in the presence of TfOH (an intimate ion pair), and (3) in the presence of MsOH (an intimate ion pair). Under each set of conditions for the reaction of 2-azetinium salt  $[4 \cdot H]^+$ , **TSs A** and **D** were more stable than **TSs B** and **C** and were the structures that produced *syn*- and *anti-3*, respectively. These results indicated that the

torquoselectivity is predominantly determined by the substituents on the ammonium nitrogen. We propose that the key interaction is a hyperconjugation between the ammonium proton (N<sup>+</sup>-H) and the  $\pi$  system of the 4-membered ring. Stabilization resulting from alignment of the filled  $\sigma_{\rm N-H}$  orbital with the unfilled  $\pi^*_{\rm C=C}$  orbital of the alkene might be expected in **TSs A** and **D** (Figure 3). In contrast, the stabilizing contribution of the interaction between the  $\sigma_{\rm N-Ar}$  orbital and the  $\pi^*_{\rm C=C}$  orbital in **TSs B** and **C** would be smaller, and an interaction between  $\sigma_{\rm N-H}$  and  $\pi^*_{\rm C=C}$  is unavailable.<sup>13</sup> A related interaction was proposed to explain torquoselectivity in the ring-opening of 2-azetine (a neutral amine). Houk et al. suggested that one of the lone pairs on the nitrogen atom controls the torquoselectivity by aligning with the  $\pi^*$  orbital of the alkene.<sup>7a</sup>

In the absence of a counteranion (Table 2, entries 1.1-1.4), **TS D** giving *anti*-**3ab** was calculated to be the most stable transition state, which is consistent with the experimental results using TfOH. When a sulfonate anion was present, **TS A** giving *syn*-**3ab** was calculated to be the most stable transition state (entries 2.1-2.4 and 3.1-3.4). These computational results agree with the MsOH-catalyzed reaction but are inconsistent with TfOH-catalyzed one. Thus, the results indicate that the ring-opening reaction of azetine **3** with strong Brønsted acid catalysts such as TfOH and Tf<sub>2</sub>NH might be preferably promoted by a solvated model. The experiment using an HBF<sub>4</sub> catalyst, which would produce a naked ammonium cation with a coordinate saturated anion (BF<sub>4</sub><sup>-</sup>), strongly supports this mechanism. However, weaker sulfonic acids such as MsOH might be favored by an ionic pair model, in which the cationic N-H moiety

intimately interacts with a counteranion. For the solvated-ion model, preference for **TS D** giving *anti*-3 over **TS A** giving *syn*-3  $(+1.4 \text{ kcal/mol})^{14}$  might be explained by the steric effect. In the *cis*-orientation, the steric repulsion of the two aromatic rings would somewhat destabilize **TS A**. For the ionic pair model, the calculated structure of **TS D** indicated steric and/or electronic repulsion between the aromatic ring on C-4 and the sulfonate anion (details for the important atomic distances of TSs A and D in the Supporting Information [SI]). Consequently, the ring-opening reaction would proceed preferably via **TS A** in the presence of MsOH or CSA (Figure 4).

To further clarify the proposed mechanisms and improve selectivity, we next examined the effect of solvents on anti/syn selectivity in the reaction of 1a with 2a (Table 3). When the reaction was carried out in a polar solvent (CH<sub>3</sub>CN) in the presence of Tf<sub>2</sub>NH, the anti-selectivity of 3aa was slightly increased relative to toluene (Table 3, entry 1 vs Table 1, entry 1). Unfortunately, the reaction did not proceed in more polar DMF (Table 3, entry 2). A considerable solvent effect was observed in the reaction with CSA. The proportion of anti-3aa versus syn-3aa increased in polar solvents such as CH<sub>3</sub>CN (entry 3), whereas nonpolar solvents, such as toluene and trifluorotoluene (TFT), led to preferable formation of syn-3aa (entries 4 and 5). The experimentally observed solvent effect supports the hypothesis that the Tf<sub>2</sub>NH- and CSA-catalyzed reactions proceed preferably via the naked cation model and the intimate ionic-pair model, respectively. Thus, the reaction using Tf<sub>2</sub>NH in a polar solvent would be optimal for selective synthesis of the anti-adduct, whereas the syn-adduct would be selectively produced by using CSA in a nonpolar solvent (details for the computational study in the SI).

Having determined the optimal conditions for selective synthesis of both isomers, we then examined the scope of the reaction using several ynecarbamates and aldimines as substrates. As shown in Table 4, *anti-* and *syn-3* were obtained in good to excellent yield and selectivity in reactions with  $Tf_2NH$  and CSA, respectively. The stereoselectivity change was also observed in the reaction of ynesultam 1d (entries 9 and 10), although no anti selectivity was observed in the reaction with  $Tf_2NH$ .

In conclusion, we have shown that external factors, such as the Brønsted acidity of the catalyst and the polarity of the solvent, affect the torquoselectivity of  $4\pi$  ring-opening of 2-azetine compounds. The inward/outward torquoselectivity may be inverted by the use of Tf<sub>2</sub>NH or CSA. This is the first successful example of a catalyst-controlled selectivity switch in electrocyclic ring-opening reactions.
