Highly Reactive and Regenerable Fluorinating Agent for Oxidative Fluorination of **Aromatics**

Krishna Murthy Janmanchi and William R. Dolbier, Jr.*

Department of Chemistry, University of Florida, Gainesville, Florida 32611-7200

Abstract:

A newly synthesized copper aluminum fluoride of nominal composition CuAl₂F₈ exhibits excellent reactivity towards direct oxidative fluorination of aromatic compounds, as well as fluorodechlorination of chloroaromatics. The spent CuAl₂F₈ reagent can be regenerated by treatment with O₂ and HF, and the fluorination process has been demonstrated to retain high conversions through 20 reaction cycles. The main advantages of this new process are safety, minimal waste, and potentially low cost.

Introduction

Fluorinated aromatic compounds are valuable synthetic intermediates for the preparation of pharmaceutical drugs, agrochemicals, and polymers.¹ However, for all practical purposes, the only way that fluorine is currently incorporated into a benzene ring commercially is the Balz-Schiemann reaction and related processes involving diazonium ion chemistry^{2,3} or under special circumstances by halex exchange of aromatic chlorine by fluorine.⁴ The diazonium processes exhibit poor atom economy and generate considerable waste. In the current study, we have sought to identify and explore new, low-cost, and environmentally benign processes for replacing aromatic hydrogen with fluorine.

There are already a number of fluorinating agents known that will either electrophilically or oxidatively replace aromatic hydrogen with fluorine,^{5–8} although few of them are effective in converting relatively unreactive benzene to fluorobenzene. These include reagents such as XeF2,69,10 CF3OF,7,11 CH3CO2F,7,12

CsSO₄F,^{7,13} various N-F^{8,14,15} and N⁺-F compounds,^{8,16,17} as well as elemental F₂ itself.⁵ However, with most of these compounds requiring F₂ for synthesis, they are all relatively expensive, generally highly toxic, and often dangerous to use, thus effectively precluding their use in commercial manufacture of fluoroaromatics.

Alternatively, fluorides of transition metals have been examined as fluorinating agents. Organic compounds, including aromatic systems, have been oxidatively fluorinated using metal fluorides such as CoF₃, KCoF₄, AgF₂, CeF₄, and MnF₃.¹⁸⁻²¹ Unfortunately such reagents have not been found to be useful for introducing only one or two fluorines into benzene or other aromatics, generally acting to exhaustively fluorinate compounds, with the result that saturated polyfluoro or perfluoro compounds are usually obtained. Moreover, they require expensive elemental F₂ to prepare or regenerate. Therefore, the discovery of a transition metal fluoride reagent that is powerful enough to fluorinate but not so reactive as to destroy an aromatic system and that can be regenerated without the need for F_2 is a noteworthy event.

In general, the relative fluorinating activities of transition metal fluorides are directly related to their respective redox potentials. For example, the fluorides of metal ions that have $E^{\circ} > 1$ comprise the potent group of fluorinating agents mentioned above that give rise to exhaustive fluorination. In contrast, fluorides of the metal ions with $E^{\circ} < 0$, such as ZnF₂, MgF₂, and AlF₃, are inert towards aromatic hydrocarbons. On the other hand, fluorides of metal ions with $1 > E^{\circ} > 0$, such as CuF₂, AgF, HgF₂, and Hg₂F₂, can act as mild fluorinating agents. In principle, all of these fluorides can be reoxidized and the fluorides regenerated by sequential or simultaneous treatment with O₂ and HF. Among these reagents, copper(II) fluoride appeared to have the greatest potential with respect to fluorinating benzene, as was demonstrated recently by Subramanian and

Manzer.²² However, only modest yields of fluorobenzene were obtained when benzene was exposed to pure CuF_2 in the gas phase at 500 °C.²³

In subsequent work on the use of CuF₂, which was a continuation of the work reported by Subramanian and Manzer, the fluorination of aromatics was examined using a physical mixture of commercial fluorides, CuF₂ with AlF₃, MgF₂, or CaF₂. Although significantly increased yields were observed (~48%),²⁴ regeneration, in particular *multiple* regeneration of the spent reagents, could not be effectively accomplished. Both oxidation of Cu to CuO at 350 °C and conversion of the oxide to CuF₂ by treatment by anhydrous HF at 400 °C are known, and such processes are dependent upon particle size.²⁵

Typically commercial metal fluorides have a tendency to form regular crystallites as a result of their high lattice energies. Therefore, upon thermal treatment, metal fluoride surface areas are on the order of 10-60 m²/g, comparable to aluminum fluorides. The fluorination ability of CuF2 depends significantly upon its surface area and the resistance of Cu to sintering under high temperature reaction conditions. Normally commercial metal fluorides are treated at high temperature and possess thermally stabilized structures. Also, mechanical mixing of commercial fluorides coupled with high temperature treatment may lead to loss of fluorine content. In contrast, one can consider the Tanabe model²⁶ for binary metal fluoride systems, where acid generation is caused by an excess of a positive or negative charge in the model structure of a binary fluoride. According to this model, when a divalent metal ion (guest) is doped with a trivalent metal ion (host), Brønsted acidic centers will be formed. Brønsted acid sites can play a key role in fluorination reactions.²⁷ The current project had as its goal the preparation of a binary fluoride system comprising CuF₂ and AlF₃.

Results and Discussion

As a result of this study, we would like to report the discovery of a metal fluoride reagent of the nominal composition $CuAl_2F_8$ that has proved very effective for carrying out direct, gas-phase, oxidative fluorination of benzene and other aromatics and which is highly regenerable. Using this $CuAl_2F_8$ reagent, conversions of benzene as high as 70% have been obtained, and multiple recycling of the reagent, in situ, using O_2 and AHF has been demonstrated. Process details and scope of the reaction are discussed below.

There are few experimental or theoretical data in the literature that might provide insight into the possible mechanism of this oxidative fluorination process. Because we detect HF as a coproduct in the benzene/CuF₂ reaction, we presume the stoichiometry of the reaction to be as shown. Cu(I) is known to bind to benzene to form π -complexes that dissociate in the gas phase, exhibiting about a 50 kcal/mol BDE.²⁸ In complexes

Scheme 2. New process of oxidative fluorination of benzene

with electron-rich benzene derivatives, such as *N*,*N*-dimethylaniline, such dissociation occurs with electron transfer to form Cu⁰ plus the aromatic radical cation.²⁹ Although there have been no similar published calculations (or experiments) related to Cu(II) π -complexes with benzene, one can be confident that such π -complexes exist (with fluoride-bound Cu(II), the complex could be $^{2}\eta$ rather than $^{6}\eta$),³⁰ and because of the larger oxidation potential of Cu(II), it is possible that dissociation of this complex would occur with electron transfer to form the benzene radical cation. Thus we could propose an overall mechanism similar to that depicted in Scheme 3. There are, of course, mechanisms other than the simple "oxidative fluorination process" of Scheme 3, but until evidence is acquired relevant to this issue, this mechanism should suffice as a working hypothesis.

Preparation of the Cu-Al Fluoride Reagents. Four solids of different composition were prepared by using CuF₂/AlF₃ molar ratios of 1:1, 1:1.5, 1:2, and 1:2.5. Appropriate amounts of Al(NO₃)₃•9H₂O and Cu(NO₃)₂•xH₂O were dissolved in ethanol. The mixture was then added dropwise to a stirred 48% hydrofluoric acid solution. After stirring for 2 h, the precipitate was filtered, washed with a small amount of distilled water/ ethanol, dried at 120 °C overnight (16 h), and calcined at 450 °C for 6 h under Ar flow.

^a Conditions: 2.5 g of reagent, 500 °C, 0.5 mL of benzene.

Typical Fluorination and Recycle Experimental Conditions. The fluorination activities of these materials were evaluated in a fixed bed reactor in the gas phase (Figure 1). About 2.5 g of reagent was loaded into a hastalloy reactor tube (8 mm o.d.) in a dry box between two plugs of silver wool. The reactor was placed in an electrically heated furnace, and the reagent was pretreated under a flow of argon gas (40 mL/ min) for 4 h at 500 °C. Benzene was introduced into the reactor using a syringe pump (flow rate, 15 mL/min; volume, 0.5 mL) along with the carrier gas (Ar, 25 mL/min) at 450–500 °C. The product mixture coming out of the reactor was condensed in a cold trap kept at 0 °C for 30 min for each pass of benzene, and the outlet from this trap was connected to an alkali trap to

neutralize the biproduct HF. The composition of the product mixture was determined by gas chromatography and ¹H and ¹⁹F NMR. Fluorobenzene was the only product at 450 °C, whereas small amounts of other products such as 1,3- and 1,2- difluorobenzene were also obtained at 500 °C. Once the reagent was expended (i.e., conversion of benzene fell to zero), the

Using this same procedure, a series of supported and unsupported CuF_2 systems were evaluated with respect to the fluorination of benzene. Pure copper(II) fluoride gave only low conversion (11%) to fluorobenzene, whereas among the supported, physically mixed systems, CuF_2/AlF_3 was the most effective towards fluorination as compared to MgF₂, CaF₂, and AgF, giving rise to 41% conversion at 500 °C (Figure 2). All such metal fluorides were commercial samples (Aldrich). Among the coprecipitated binary fluoride systems, CuF_2/AlF_3 at a ratio of 1:2 was found to exhibit optimal fluorinating ability in the fluorination of benzene (Table 1).

Regarding benzene fluorination, AlF₃ was found to be totally inactive, which indicates that it acts only as a support to disperse CuF₂. Comparing the coprecipitated reagent of nominal composition CuAl₂F₈ with the CuF₂/AlF₃ mixture, the binary fluoride exhibits greater reactivity (56%) compared to that of the physically mixed, commercial CuF₂ and AlF₃ under identical conditions (Table 1). We believe that the observed high activity of the binary fluoride might be due to the CuF₂ being highly dispersed within the AlF₃ support. At the present time, we cannot be certain whether the fluorinating reagent constitutes a separate CuAl₂F₈ phase or whether the synthesis conditions simply provide a good basis for forming a very amorphous, finely distributed CuF₂ reagent.

Fluorination of aromatics using inorganic metal fluorides in the gas phase is a "solid–gas" reaction. Normally in solid–gas reactions, once the surface CuF_2 has become reduced to Cu(0), sintering of copper can begin to occur at the high temperature of reaction. As a result of the process of coprecipitating CuF_2 with AlF₃ followed by heating and treatment with HF, it has been possible to obtain a high dispersion of CuF_2 within the AlF₃ support, such that sintering can be minimized, if not prevented, even at high temperature. By selecting aluminum fluoride, an acidic (Lewis acid) support, to deposit copper fluoride, it has been possible to obtain highly dispersed copper fluoride species on aluminum fluoride.

The copper aluminum fluoride systems (both the commercial and coprecipitated) were tested in multiple cycles, in the oxyfluorination of benzene. After the initial activity experiment (single pass of benzene), the carrier gas was switched off, and the reactor was connected to the flow of anhydrous hydrogen fluoride (8 mL/min) and oxygen gases (10 mL/min) for 2.5 h. Then the reactor was flushed with argon for 0.5 h, and the reaction cycle (fluorination of benzene) was repeated. The coprecipitated copper aluminum fluoride remained very active and stable during multiple cycles, whereas when using the commercial metal fluoride mixture, the benzene conversion fell to zero within 3 cycles.

Thus the benzene– CuF_2 (copper aluminum fluoride) reaction has been demonstrated to be a two-phase, cyclic process in which generation of the CuF₂ in situ from copper metal by successive reaction with oxygen and hydrogen fluoride at 500 °C was followed by reaction with benzene, the cycle being completed by reconversion of the copper metal residue back to CuF₂ followed by further reaction with benzene to obtain virtually identical yields of fluorobenzenes in each cycle. The binary fluoride system was found to be very stable through 20 recycled experiments, exhibiting constant activity of ~45% conversion with almost 80% selectivity towards monofluorobenzene (Figure 3).

X-ray diffraction patterns of the copper aluminum fluoride reagent are shown in Figure 4. In the fresh sample (calcined at 450 °C under Ar for 4 h), before reacting with benzene, crystalline phases due to AlF₃ are mainly seen along with very weak signals due to CuF₂, which indicates that the CuF₂ is mostly dispersed within the AlF₃. In the XRD pattern of the spent system (after reacting with benzene), strong crystalline signals due to Cu(0) appear as a result of the reaction of CuF₂ with benzene to form fluorobenzene. Crystalline signals of CuF₂ and loss of Cu(0) signals in the XRD pattern of the recycled material can be seen. This indicates that CuF₂ has been regenerated by treatment with oxygen and HF.

The copper aluminum fluoride has also been characterized by scanning electron microscopy (SEM) and energy dispersive spectrometry. A fresh sample (before reaction with benzene) exhibits uniform morphology and the presence of a high concentration of fluoride on the surface (Figure 5a). In the partially spent binary fluoride material (after limited reaction with benzene), a fine distribution of copper can be seen (Figure 5b). This indicates that the copper is not sintered or agglomerated even at the high reaction temperature. Thus, as mentioned above, it has apparently been possible to prevent copper sintering by use of the highly dispersed binary reagent when using limited amounts of benzene, under which conditions the Cu(II) is not exhaustively reduced. In the regenerated binary fluoride material, after 20 cycles, surface analysis shows a uniform morphology with a high concentration of fluoride (Figure 5c).

This new copper aluminum fluoride reagent has also been found to be active in fluorinating monofluorobenzene and pyridine (Table 2), with 1,3-difluorobenzene and 2-fluoropyridine being obtained as major products in those reactions, respectively.

In addition, the reagent of nominal composition $CuAl_2F_8$ has been found to be effective in converting chloroaromatics to fluoroaromatics. Results for the reactions of chlorobenzene, dichlorobenzenes, chlorotoluenes and chlorofluorobenzenes are summarized in Tables 3 and 4, with the fluorination of 1-chloronaphthalene being shown in Scheme 4.

Other than results presented in our recent related patent, which claimed low conversions of chloroaromatics to fluoroaromatics using either CuF₂ (500 °C) or AgF (350 °C), there appear to be no reports of fluorodechlorination of chloro aromatics, other than classic S_NAr reactions, such as the reaction of *p*-chloronitrobenzene with fluoride ion.³¹ On the other hand, cuprous salts (sometimes with Cu(II) catalysis) have long been known to promote replacement of unactivated aryl halogens

with nucleophiles,³² the best known example being the conversion of aryl bromides to aryl nitriles through reaction with CuCN.^{33,34} Less known is the little studied conversion of aryl bromides to chlorides through treatment with CuCl,^{35,36} which is shown in Scheme 5.

To our knowledge, however, there have been no previous reports of the use of a transition metal fluoride to convert a nonactivated aryl chloride to an aryl fluoride. As one can see from the tables, the reaction is not regiospecific and thus cannot involve a simple Cl-F replacement process. The study of this

reaction is still in its preliminary stages, and thus we will refrain from speculating about a possible mechanism.

Conclusions

The newly synthesized copper aluminum fluoride of nominal composition $CuAl_2F_8$ exhibits improved activity towards fluorination of aromatic compounds in comparison to the physical mixture of commercial CuF_2 and AlF_3 . It has also been shown to maintain reactivity through 20 reaction cycles of regeneration. The high fluorination ability and recyclability of the binary fluoride might be due to the high dispersion of CuF_2 on AlF_3 , which combined with the use of limited amounts of benzene in each run seems to inhibit sintering of copper.

The main advantages of this new process are (1) safety; the process design avoids the possibility of runaway reactions that can be encountered when using the diazonium ion based synthesis, and (2) minimal waste; with virtually no waste, the new process is extremely environmentally friendly. When this is combined with the ability to recycle the Cu reagent, the cost of the process should also be very attractive.
