S Supporting Information

ABSTRACT: A catalytic method for enantioselective synthesis of homoallylamides through Cu-catalyzed reactions of stable and easily accessible (pinacolato)allylborons with aryl-, heteroaryl-, alkyl-, or alkenyl-substituted Nphosphinoylimines is disclosed. Transformations are promoted by 1-5 mol % of readily accessible NHC-Cu complexes, derived from C₁-symmetric imidazolinium salts, which can be prepared in multigram quantities in four steps from commercially available materials. Allyl additions deliver the desired products in up to quantitative yield and 98.5:1.5 enantiomeric ratio and are amenable to gram-scale operations. A mechanistic model accounting for the observed selectivity levels and trends is proposed.

Tomoallylic amines are imbedded within structures of many Honoallync annues are noted at an serve as entities for the preparation of myriad N-containing molecules.^{1,2} Development of efficient and enantioselective allyl additions to aldimines, a direct approach for accessing chiral homoallylic amines, is thus a compelling objective in chemical synthesis. Enantiomerically pure allyl-containing reagents, used in stoichiometric quantities, react efficiently and diastereoselectively with aldimines; the utility of these strategies has been demonstrated in complex molecule synthesis.³ Substrates containing a chiral auxiliary can participate in highly diastereoselective allyl additions.⁴ Such an approach, however, requires especially reactive allylmetals (e.g., Grignard reagents^{4a} or allylzincs^{4g}) that could be intolerant of a number of key functional groups and/or preparation of which might be complicated; alternatively, stoichiometric quantities of costly allylindiums^{4b-f} and/or Pd-based catalysts are needed.^{4b,e} Several reports have demonstrated that chiral catalysts promote additions of allyl groups to aldimines.⁵⁻⁸ Nonetheless, such protocols also demand precious indium salts (at times in stoichiometric amounts or more)^{δ} or require allyl reagents that are highly toxic^{8a} or relatively unstable (so that high reactivity is achieved);7b some reported catalytic enantioselective approaches are operative with imines derived from activated aldehydes (e.g., glyoxylates) $^{5-7}$ or furnish products that necessitate somewhat harsh or costly conditions for conversion to the unprotected amine. $^{5-8}$ A reasonably general, costeffective, and functional group tolerant catalytic enantioselective process thus remains lacking. We outline a method for the synthesis

Scheme 1. Catalytic Cycle for Reaction of (Pinacolato)allylboron with Aldimines Promoted by an NHC-Cu Complex [B(pin) = pinacolatoboron]

of enantiomerically enriched homoallylamides by reactions of stable allylboron reagents that can be either purchased or easily prepared. Transformations are performed with an inexpensive Cu salt and 1-5 mol % of chiral C_1 -symmetric imidazolinium salts,⁹ multigram quantities of which can be synthesized from commercially available materials by a straightforward four- to five-vessel protocol (\sim 30%) overall yield). Complete conversion is observed in 6-18 h; the desired products are isolated in 61% to >98% yield and in up to 98.5:1.5 enantiomer ratio (er). Conversion of the resulting Nphosphinoylamides to the derived amines can be effected under aqueous acidic conditions, as demonstrated previously.¹⁰

The present investigations were conceived as a result of our interest in designing catalytic transformations promoted by Nheterocyclic carbene (NHC) copper complexes generated in situ by an initial reaction with a boron-based reagent.^{9b,c,11} We surmised that reaction of Cu-alkoxide i with (pinacolato)allylboron 1 should afford NHC-Cu-allyl ii (Scheme 1), a process driven by the formation of the energetically favorable B-O bond. We have previously adopted a similar strategy with B-B¹¹ and B-Si^{9b} reagents to generate NHC-Cu-B complexes or the corresponding silanes, which participate in enantioselective C-B or C-Si bond forming reactions. We sought to examine whether the above approach might be utilized such that the B-C bond reacts with an NHC-Cu-alkoxide to yield a catalytically active NHC-Cu-C system (vs NHC-Cu-B or NHC-Cu-Si).12 The resulting

^{*a*} Reactions performed under N₂ atmosphere with 2.0 equiv of 1. ^{*b*} Values determined by analysis of 400 MHz ¹H NMR spectra of unpurified mixtures. ^{*c*} Values determined by HPLC analysis; see the Supporting Information for details. Mes = $2,4,6-(Me)_3C_6H_2$.

NHC-Cu-allyl ii could undergo reaction with an *N*-phosphinoylimine to initiate C-C bond formation, furnishing iii. Catalyst release might occur either by σ -bond metathesis between the Cu-O bond of iii and the C-B of another molecule of 1 to generate the boronic ester derivative of the desired product¹³ or through the agency of an alcohol additive.¹⁴

To probe the feasibility of the envisioned catalytic cycle, we investigated the ability of various chiral NHC-Cu complexes to catalyze the reaction of 7a and 1 (Table 1). Catalysts were formed and utilized in situ by treatment of the corresponding imidazolinium salts with NaOt-Bu and CuCl; MeOH filled the role of a proton source. Bidentate Cu complexes derived from phenol 2 or sulfonate 3 (entries 1, 2) readily promote transformation but deliver 8a with minimal stereoselectivity. Similarly high efficiency and inferior enantioselectivity are obtained with C_2 -symmetric 4a,b (entries 3, 4). Enantiomeric purity is improved when C_1 -symmetric NHC-Cu complexes derived from 5a-5c or 6a serve as catalysts (entries 5-8).

However, it is through the use of **6b** (entry 9, Table 1), bearing an *o*-substituted mesitylphenyl as its dissymmetric *N*-aryl group, that, without any diminution in efficiency (>98% conv), a significantly improved er is achieved (91:9 er). Incorporation of a *m*-isopropyl unit, beneficial in certain previous studies (**6c**, entry 10),^{9b} does not enhance selectivity. Performing the reaction with 1.4 equivalents of **1** at -50 °C, under otherwise identical conditions, delivers **8a** in 95% yield and 97:3 er (entry 1, Table 2).

A variety of aryl-substituted substrates can be used; the resulting homoallylamides are isolated in 88% to >98% yield

Scheme 2. NHC-Cu-Catalyzed Enantioselective Allyl Addition to Heteroaryl-Substituted Phosphinoylimines^{*a*}

^{*a*} Performed under the conditions shown in Table 2 with **6b** (for **9** and **11**) or **6d** (for **10**) as the imidazolinium salt. Conversions and selectivities determined as indicated in Table 2; yields of isolated and purified products (\pm 5%).

and 96:4–98.5:1.5 er (Table 2). Electron-deficient aldimines (entries 3, 4, 7–10) as well as those containing an electrondonating substituent (entries 6 and 11), undergo facile transformation to afford products in \geq 97:3 er. In the case of sterically congested aldimines 7**b**,**e**,**f** (entries 2, 5, 6), and 7**k**, the latter of which contains a *p*-methoxyphenyl unit (entry 11), higher enantioselectivity is achieved with the NHC–Cu complex derived from 6d [7**b**,**e**,**f**,**k** in 84:16–87.5:12.5 er (>98% conv) with 6**b**]. The catalytic protocol can be performed with aldimines bearing a heteroaromatic unit (9–11, Scheme 2).

Similar to **6b**, **6d** is C_1 -symmetric but bears two dissymmetric N-Ar units, existing as a 5:1 mixture of stereoisomers in solution (determined by analysis of 400 MHz ¹H NMR); imidazolinium salt **6d** is used as a mixture of isomers. The X-ray structure of the major isomer of **6d** is shown in Figure 1; the same conformer is predominant in solution, as established by nOe experiments.¹⁵ Whether both of the derived NHC–Cu complexes promote reaction and the facility with which the two stereoisomers undergo interconversion (after complexation) is unclear.¹⁶

Figure 1. Nuclear Overhauser effect (nOe) experiments and X-ray structure, indicating the identity of the major isomer of imidazolinium salt **6d** (5:1; see the Supporting Information for details).

Scheme 3. NHC-Cu-Catalyzed Enantioselective Allyl Addition to Alkyl-Substituted Phosphinoylimines^{*a,b,c*}

^{*a*} Performed under identical conditions for *R*-13. Conversions and selectivities determined as indicated in Table 2; yields are of the purified products (\pm 5%). ^{*b*} With catalyst derived from 6d. ^{*c*} Performed with 5.0 mol % of 6d and CuCl and 12 mol % NaOt-Bu.

A difficult class of substrates consists of alkyl-substituted imines, $^{5-8,17}$ which can be converted to the derived homoallylic amines in high enantiomeric purity (13–16, Scheme 3). Contrary to aldimines that bear a linear (e.g., 13 in 97:3 er) or β -branched (e.g., 14 in 96:4 er) group, enantioselectivity is diminished with an α -substituted alkyl unit (cf. 15 in 81:19 er). The highly enantioselective generation of diene 16 with the Cu complex derived from 6d demonstrates that enal-derived aldimines are suitable substrates as well (85:15 er and >98% conv with 6b).

Another class of allyl-containing agents that has received less attention is 2-substituted allylboronates such as methyl- and phenyl-containing 17a,b (eq 1).^{5,8a,18} Cu-catalyzed reactions are promoted, albeit with a higher catalyst loading and longer reaction times (5.0 mol % 6d or 6b), to deliver 18a,b in 96% and 91% yield and 95:5 and 91:9 er, respectively. Transformations with *E*- or *Z*-crotylborons proceed efficiently and with appreciable enantioselectivity (85:15–90:10 er), but diastereo-selectivities are low (~60:40 dr).

As shown in eq 2, the enantioselective Cu-catalyzed transformation can be performed on a reasonable laboratory scale (1.0 g)with only 1.0 mol % of the chiral catalyst. In the case of homoallylamide 8a, material of high enantiomeric purity (97.5:2.5 er) is isolated in 75% yield by simple filtration without resorting to silica gel chromatography.

Figure 2. Model for origin of enantioselectivity in NHC–Cu-catalyzed allyl additions to *N*-phosphinoylimines.

Several mechanistic issues merit a brief discussion. There is <5% conversion in the absence of MeOH under catalytic conditions. With stoichiometric amounts of the NHC-Cu complex, the desired homoallylamine is obtained without the protic additive. These observations indicate that the role of the additive is in connection with the release of the NHC−Cu catalyst (i.e., iii→i in Scheme 1 with ROH = MeOH). The facile formation of various homoallylamines under conditions that include 1-5 mol % catalyst loading but 1 and 2 equiv of aldimine and MeOH, respectively, indicates that the rate of reaction of NHC-Cu-allyl complexes (cf. ii) with aldimines is substantially faster than adventitious protonation of the C-Cu bond of the allylmetal intermediate. Reaction with d_2 -(pinacolato)allylboron (labeled at C3) leads to complete scrambling of deuterium at C1 and C3, suggesting the intermediacy of π -allylcopper and providing a rationale for low diastereoselectivity with the crotylboron reagents.

Modes of reaction I-II (Figure 2) may be used to account for the stereochemical outcome of the Cu-catalyzed processes. Coordination of the N-phosphinoylimine's Lewis basic oxygen is likely the key contact point that brings substrate and catalyst together. The less Lewis basic N may be weakly associated with the transition metal. Involvement of the Lewis basic P-O of the aldimine substrate offers a rationale for the high er values observed with Nphosphinoyl-derived imines versus the corresponding o-anisidylimines, which react readily under the same conditions but deliver racemic products.¹⁹ Molecular models suggest that a preference for the reaction via I versus the competing modes of reaction, such as that represented by II, might be due to subtle variations in catalystsubstrate interactions. Steric repulsion between the protruding Me unit and the aldimine substituent (G) in I appears to be less severe than that existing between a phenyl group of the phosphinoyl moiety in II (Figure 2); this difference might arise from tighter binding of the phosphinoyl oxygen with the Lewis acidic Cu, compared to the imine nitrogen. Superior enantioselectivities with 6d (vs 6b), particularly in the case of sterically congested aldimines, may be attributed to the tilt of the NAr moiety (Figure 1), lifting the resident o-Me group to accommodate the substrate molecule better. Such conformational change leads to an improvement in enantioselectivity since it may not sufficiently reduce the more severe interaction in II. It should be noted that the identity of the stereochemistry-determining step has not been determined and the energetics of the catalytic cycle might vary with different substrates. The models in Figure 2 are meant to serve primarily for the prediction of the stereochemical preferences.
