 Supporting Information

ABSTRACT: Although fluorescent proteins have been utilized for a variety of biological applications, they have several optical limitations, namely weak red and near-infrared emission and exceptionally broad (>200 nm) emission profiles. The photo-physical properties of fluorescent proteins can be enhanced through the incorporation of novel cofactors with the desired properties into a stable protein scaffold. To this end, a fluorescent phosphorus corrole that is structurally similar to the native heme cofactor is incorporated into two exceptionally stable heme proteins: H-NOX from *Caldanaerobacter subterraneus* and heme acquisition system protein A (HasA) from *Pseudomonas aeruginosa*. These yellow-orange emitting protein conjugates are examined by steady-state and time-resolved optical spectroscopy. The HasA conjugate exhibits enhanced fluorescence, whereas emission from the H-NOX conjugate is quenched relative to the free corrole. Despite the low fluorescence quantum yields, these corrole-substituted proteins exhibit more intense fluorescence in a narrower spectral profile than traditional fluorescent proteins that emit in the same spectral window. This study demonstrates that fluorescent corrole complexes are readily incorporated into heme proteins and provides an inroad for the development of novel fluorescent proteins.

Corrole-Substituted Fluorescent Proteins

■ INTRODUCTION

Since the discovery of green fluorescent protein (GFP)¹ and its subsequent demonstration as a fluorescent tag for *in vivo* labeling,² the field of fluorescent proteins has greatly expanded. Significant effort has been dedicated to tune the optical properties of fluorescent proteins, spanning ultraviolet (UV), visible, and near-infrared (NIR) wavelengths. Moreover, fluorescent proteins have been utilized for a variety of applications as sensitizers, labels, and sensors.³ Despite advances to extend the emission of fluorescent proteins into the red and NIR, the emission intensity of these proteins is quite weak, exhibiting quantum yields (ϕ) < 20%.⁴ Since tissue is transparent to red and NIR light in the 600–1100 nm range (*i.e.*, the “tissue transparency window”),⁵ the weak emission of traditional fluorescent proteins in this spectral range greatly limits *in vivo* utility. Indeed, the quantum yields of traditional red fluorescent proteins are significantly lower than typical GFPs and other fluorescent proteins that emit outside the tissue transparency window. Another limitation of traditional fluorescent proteins is their broad emission profiles, which can span over 200 nm. This limits the utility of fluorescent proteins for ratiometric sensing applications. In this sensing modality, two fluorophores are incorporated into the sensor and the analyte is quantified by measuring the emission intensity ratio of the two components. This is a robust sensing methodology that is independent of sensor concentration and is functional in scattering media, such as the biological milieu.^{6–8}

One strategy to improve upon the optical properties of traditional fluorescent proteins is to incorporate a highly fluorescent cofactor into a stable protein scaffold. One example of such a scaffold is the heme nitric oxide/oxygen binding (H-NOX) protein from the thermophilic bacterium *Caldanaerobacter subterraneus* (Cs) (Figure 1a). H-NOX proteins are a family of bacterial gas-sensing proteins that are homologous to the heme domain of the mammalian nitric oxide receptor soluble guanylate cyclase (sGC).^{9–15} They have a buried, hydrophobic heme pocket comprising a heme-ligating histidine residue and a conserved Y–S–R motif that hydrogen bonds with the propionate chains of the heme cofactor. In oxygen-sensing H-NOXs, such as Cs H-NOX, the protein also contains a distal hydrogen-bonding network that stabilizes the O₂ adduct. The iron center of the heme cofactor binds diatomic gases, such as NO or O₂, resulting in a conformational change of the protein. This triggers a signal cascade that culminates in a physiological response to the gaseous signal, such as biofilm formation or flagellar motion.¹⁵ The robust Cs H-NOX protein is readily expressed in *Escherichia coli*, variants are easily made, and it

readily binds unnatural heme cofactors. Together, these properties render Cs H-NOX an ideal platform to construct novel sensing and imaging agents.¹⁶ To this end, Cs H-NOX has been tailored for a variety of applications, including NO sensing,¹⁷ O₂ sensing,¹⁸ magnetic resonance imaging,¹⁹ and fluorescent labeling.²⁰

Another stable protein scaffold is the heme acquisition system protein A (HasA) from the pathogenic bacterium *Pseudomonas aeruginosa* (Pa) (Figure 1b). Under iron-depleted stress conditions, these bacteria secrete HasA to scavenge heme from the host and subsequently import it through a membrane receptor HasR.^{21–24} Unlike H-NOX proteins, HasA has a surface-exposed heme-binding pocket. The secreted apoprotein exhibits an extended conformation; two flexible loops sequester the heme cofactor, leading to high-affinity binding ($K_a = 5.3 \times 10^{10} \text{ M}^{-1}$)²⁵ and a large conformational change.²⁶ The bound heme is ligated by a tyrosine and a histidine residue, but it has been demonstrated that either one of these two residues alone is sufficient to bind heme.^{27,28} In addition to the native heme cofactor, Pa HasA can also bind a variety of β -alkyl and meso-aryl iron porphyrins, as well as related iron phthalocyanine and salophen complexes.^{29,30} It has also been demonstrated that HasA can bind gallium complexes of protoporphyrin IX^{31,32} and phthalocyanine.³³

Since both H-NOX and HasA bind artificial cofactors, a strategy to incorporate fluorescent analogues of protoporphyrin IX (Chart 1) was designed to serve as an alternative to traditional fluorescent proteins. Although emissive in the red region of the spectrum, free-base and metalloporphyrins are not exceptionally bright fluorophores. For example, Zn(II)

Chart 1. Comparison of the Native Heme Cofactor Protoporphyrin IX and the Corrole Analog Utilized in This Study.

porphyrin complexes exhibit $\phi = 4\text{--}5\%$,³⁴ which is not an improvement over extant fluorescent proteins. Corrole is a closely related tetrapyrrole macrocycle with a contracted 23-atom core due to the presence of a direct pyrrole-pyrrole linkage.³⁵ As a result, corrole is a trianionic ligand when fully deprotonated, rather than dianionic like porphyrin, thereby stabilizing different metal complexes and accessing different molecular properties.^{36,37} While corroles have not been studied as extensively as their porphyrin congeners, it has been demonstrated that they exhibit optical properties superior to related porphyrin complexes.³⁸ In general, corroles have higher fluorescent quantum yields than related porphyrin complexes.^{39,40} Specifically, light main group corrole complexes of gallium,^{39,41} phosphorus,^{42–44} aluminum,^{40,41,45,46} and silicon^{47,48} are highly fluorescent and have been utilized for biological imaging applications.^{43,49–51} Therefore, main group corrole complexes are ideal heme analogues for fluorescent protein development.

To this end, the synthesis of a corrole analog that is structurally similar to the native heme cofactor was targeted (Chart 1) for ultimate reconstitution into the heme pocket of the apoprotein to furnish a novel fluorescent protein. Previous studies have examined corrole-protein interactions with a variety of proteins, including serum albumin,^{52,53} viral capsids,⁵⁴ and transferrin.⁵⁵ Additionally, nanoparticle formulations have been prepared with corrole conjugates of these proteins.^{56,57} In all of these examples, the corroles are amphiphilic meso-aryl corroles with β -sulfonate substituents. These conjugates, which exploit nonspecific hydrophobic and charge interactions, have been utilized for a variety of biomedical applications,⁵¹ including drug delivery,⁵⁴ *in vitro* cancer cell therapy,⁵⁴ cell imaging,⁵⁶ and sonodynamic therapy.⁵⁷ Conversely, only two studies have used heme-like (meso-unsubstituted, β -octaalkyl) corrole complexes to replace the native porphyrin cofactor of heme proteins: an iron corrole in myoglobin and horseradish peroxidase (HRP) as artificial peroxidases⁵⁸ and a copper corrole in myoglobin.⁵⁹ Here, this approach has been extended by developing fluorescent H-NOX and HasA proteins using a phosphorus corrole as the fluorescent cofactor.

EXPERIMENTAL SECTION

Materials for Chemical Synthesis and Characterization. The following chemicals were used as received: dichloromethane (CH₂Cl₂), ethyl acetate (EtOAc), hexanes, 4-(dimethylamino)pyridine, 3-nitro-2-butanol (mixture of isomers), acetic anhydride (Ac₂O), sodium bicarbonate (NaHCO₃), sodium sulfate (Na₂SO₄), ethyl isocyanacetate, benzyl acetoacetate, methyl 4-acetyl-5-oxohexanoate, zinc powder (Zn), triethylamine (NEt₃), trimethyl orthoformate, L-histidine hydrochloride monohydrate, palladium on carbon with 10 wt % loading (Pd/C), silica gel (60 Å pore size, 230–400 mesh particle size), potassium

hydroxide (KOH), concentrated hydrobromic acid (HBr), pyridine, phosphorus trichloride (PCl_3), rhodamine 101, and Celite from Sigma-Aldrich; trifluoroacetic acid (TFA), concentrated hydrochloric acid (HCl), sodium hydroxide (NaOH), and tetrahydrofuran (THF) from EMD Millipore; methanol (MeOH), chloroform (CHCl_3), sodium nitrite (NaNO_2), and 85% phosphoric acid (H_3PO_4) from Fisher Scientific; acetic acid (HOAc) from Macron; tetrachloro-1,4-benzoquinone (*p*-chloranil) from TCI Chemicals; chloroform- d (CDCl_3) and dimethylsulfoxide- d_6 ($\text{DMSO}-d_6$) from Cambridge Isotope Labs; hydrogen gas (H_2) from Praxair; lead(IV) acetate ($\text{Pb}(\text{OAc})_4$) from Alfa Aesar; and potassium carbonate (K_2CO_3) from J. T. Baker Chemicals. Nitrogen gas (N_2) from Praxair was passed over a Drierite column prior to use. The phosphorus complex of 5,10,15-tris(4-methoxyphenyl)-corrole was prepared as previously reported.⁴²

Materials for Protein Expression, Purification, and Reconstitution. The following chemicals were used as received: potassium phosphate dibasic trihydrate (K_2HPO_4), deoxyribonuclease I from bovine pancreas (DNase), benzamidine, D-(+)-glucose, triethanolamine (TEA), 2-morpholinoethanesulfonic acid (MES), and antifoam SE-15 from Sigma-Aldrich; Luria Broth (LB), Terrific Broth (TB), ampicillin, and 4-(2-aminoethyl)benzenesulfonyl fluoride hydrochloride (AEBSF) from Research Products International; agarose, DMSO, BugBuster Master Mix, and Immobilon Classico Western HRP substrate from EMD Millipore; hemin chloride from Frontier Scientific; PrimeSTAR Max DNA polymerase and His60 Ni Superflow resin from Takara Bio; mouse anti-His₆ antibody and goat anti-mouse HRP conjugate antibody from Life Technologies; Bacto Agar from BD; glycerol from VWR; lysozyme (from egg white) from Amresco; TEA hydrochloride (TEA-HCl) from Spectrum Chemical; imidazole from Oakwood Chemical; sodium chloride (NaCl) from Macron; Gibson Assembly Master Mix from New England BioLabs; nitrogen gas (N_2) from Praxair; isopropyl β -D-1-thiogalactopyranoside (IPTG) and ethylenediaminetetraacetic acid disodium salt dihydrate (EDTA) from Fisher Scientific; and PD-10 desalting columns (Sephadex G-25 medium) from GE Healthcare. Argon gas (Ar) from Praxair was passed over an Oxiclear gas purifier prior to use. The DH5 α and XL1-Blue *E. coli* competent cells were obtained from the UC Berkeley Macrolab, while the RP523(DE3) competent cells were obtained from lab-generated stocks.¹³

8,12-Bis(2-methoxycarbonyl)ethyl)-2,3,7,13,17,18-hexamethyl Corrole ($\text{H}_3\text{-2}$). In a 20 mL glass vial, 60 mg (83 μmol) of *a,c*-biladiene **1**, which was prepared as described in the Supporting Information, was suspended in 10 mL of MeOH. The mixture was briefly sonicated and 65 mg (264 μmol) of *p*-chloranil was added. The mixture was briefly sonicated and then stirred at room temperature for 1.5 h. Two parallel reactions were run and then combined for work-up and purification. The reaction mixtures were transferred to a separatory funnel and CH_2Cl_2 was added. The red-brown solution was washed with a saturated solution of NaHCO_3 and then with water. The organics were dried over Na_2SO_4 and brought to dryness. The crude material was loaded onto a silica gel column packed with CH_2Cl_2 , and the product was eluted with 4:1 CH_2Cl_2 :EtOAc as a magenta solution. The solvent was removed by rotary evaporation to afford 77 mg (83% yield for two parallel reactions, or 120 mg of **1**) of the title compound as a purple solid. ^1H NMR (400 MHz, CDCl_3 , 25 $^\circ\text{C}$): δ 3.19 (t, J = 7.7 Hz, 4H), 3.35 (s, 6H), 3.45 (s, 6H), 3.53 (s, 6H), 3.71 (s, 6H), 4.23 (t, J = 7.7 Hz, 4H), and 9.19 (s, 1H), 9.35 (s, 2H). Anal. Calcd for $(\text{M} + \text{H})^+ \text{M} = \text{C}_{33}\text{H}_{38}\text{N}_4\text{O}_4$, 555.2966. Found: ESI-MS: 555.2960. UV-vis (CHCl_3), λ in nm (ϵ in $10^3 \text{ M}^{-1} \text{ cm}^{-1}$): 398 (130.), 409 (97.8), 501 (7.0), 538 (16.3), 550 (16.6), and 593 (17.5).

8,12-Bis(2-methoxycarbonyl)ethyl)-2,3,7,13,17,18-hexamethylcorrolato-(oxo)phosphorus(V) (P-2). In a 20 mL glass vial, 21 mg (38 μmol) of free-base corrole $\text{H}_3\text{-2}$ was dissolved in 5 mL of dry pyridine and 100 μL of PCl_3 (0.16 g, 1.1 mmol) was added; the resultant mixture was stirred at room temperature for 10 min. An additional 200 μL of PCl_3 (0.31 g, 2.3 mmol) was added and the mixture was stirred at room temperature for 10 min. Then 200 μL of PCl_3 (0.31 g, 2.3 mmol) was added and the mixture was stirred at room temperature for 10 min. The reaction mixture was dissolved in CH_2Cl_2 and transferred to a separatory funnel; water was carefully added to react with the residual

PCl_3 . The product was extracted into CH_2Cl_2 , and the organic layer was washed with a saturated solution of NaCl. The organics were dried over Na_2SO_4 and brought to dryness. The crude material was loaded onto a silica gel column packed with EtOAc and the product was eluted with 5% MeOH in EtOAc as a pink-orange solution. The solvent was removed by rotary evaporation to afford 18 mg (77% yield) of the title compound as a red-orange solid. ^1H NMR (400 MHz, CDCl_3 , 25 $^\circ\text{C}$): δ 3.25 (m, 4H), 3.57 (s, 6H), 3.63 (s, 6H), 3.70 (s, 6H), 3.77 (s, 6H), 4.38 (t, J = 7.8 Hz, 4H), 9.87 (s, 2H), and 9.96 (s, 1H). ^{31}P NMR (162 MHz, CDCl_3 , 25 $^\circ\text{C}$): δ -98.76. Anal. Calcd for $(\text{M} + \text{H})^+ \text{M} = \text{C}_{33}\text{H}_{35}\text{N}_4\text{O}_5\text{P}$, 599.2418. Found: ESI-MS: 599.2410. UV-vis (CHCl_3), λ in nm (ϵ in $10^3 \text{ M}^{-1} \text{ cm}^{-1}$): 274 (16.9), 280 (16.2), 313 (12.3), 399 (215), 403 (238), 485 (3.4), 517 (11.6), 522 (11.2), and 558 (25.3).

8,12-Bis(2-carboxyethyl)-2,3,7,13,17,18-hexamethylcorrolato-(oxo)phosphorus(V) (P-3). In a 50 mL round bottom flask, 29 mg (47 μmol) of corrole ester P-2 was dissolved in 10 mL of THF and 10 mL of 3 M NaOH was added. The biphasic mixture was stirred vigorously and refluxed overnight, protected from light. After this reaction, the corrole had transferred from the organic layer to the aqueous layer. The reaction mixture was cooled in an ice bath and acidified by slowly adding 1 M HCl to reach pH \sim 0. The solution became cloudy, indicating precipitation of the protonated carboxylic acid corrole. The red-orange suspension was transferred to a 50 mL conical tube and was centrifuged at 4300g for 20 min. The supernatant was discarded and the pellet was resuspended in 20 mL of H_2O , and the suspension was centrifuged at 4300g for 20 min. This process was repeated until the supernatant had a pH of \sim 5. The pellet was resuspended in a minimal amount of H_2O and transferred to a round bottom flask. The solvent was removed by rotary evaporation and then dried under vacuum for several days to afford 20 mg (76% yield) of the title compound as a dark red solid. ^1H NMR (400 MHz, $\text{DMSO}-d_6$, 25 $^\circ\text{C}$): δ 3.13 (t, J = 7.6 Hz, 4H), 3.54 (s, 6H), 3.62 (s, 6H), 3.63 (s, 6H), 4.32 (m, 4H), 10.09 (s, 2H), 10.17 (s, 1H), and 12.39 (bs, 2H). ^{31}P NMR (162 MHz, $\text{DMSO}-d_6$, 25 $^\circ\text{C}$): δ -97.66. Anal. Calcd for $(\text{M} + \text{H})^+ \text{M} = \text{C}_{31}\text{H}_{31}\text{N}_4\text{O}_5\text{P}$, 571.2105. Found: ESI-MS: 571.2110.

Protein Expression and Purification. The protein expression plasmids were prepared as described in the Supporting Information. The plasmids were transformed into the RP523(DE3)¹³ strain of *E. coli*, and then grown on an LB agar plate (1.5% (w/v) agar) supplemented with ampicillin (100 $\mu\text{g}/\text{mL}$) and hemin (20 $\mu\text{g}/\text{mL}$). Ten colonies were selected to test protein expression and were grown in 3 mL of TB supplemented with ampicillin (100 $\mu\text{g}/\text{mL}$) and hemin (20 $\mu\text{g}/\text{mL}$) at 37 $^\circ\text{C}$ overnight. Glycerol stocks were prepared for each culture. The cells were then subcultured (1:200 dilution) in 50 mL of TB supplemented with ampicillin (100 $\mu\text{g}/\text{mL}$), hemin (20 $\mu\text{g}/\text{mL}$), and 0.2% (w/v) glucose and grown at 37 $^\circ\text{C}$ until the OD₆₀₀ reached \sim 0.6. IPTG was added (100 μM final concentration) and the cultures were then transferred to an 18 $^\circ\text{C}$ incubator and grown overnight. H-NOX expression levels were determined by preparing cell density-matched samples of each culture, as well as a pre-induction control. The cells were pelleted (2300 g for 5 min), then lysed using BugBuster, and the whole-cell lysate was analyzed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and Western blot to identify His-tagged proteins. Western blotting was performed using a mouse anti-His₆ primary antibody, a goat anti-mouse-HRP conjugate secondary antibody, and the Classico HRP substrate. Colonies with the highest level of heme expression were then selected for large-scale protein expression. For large-scale expression of the holoprotein, a 5 mL overnight culture (prepared as described above) was inoculated directly from a frozen glycerol stock and then grown at 37 $^\circ\text{C}$ overnight. This culture was then used to inoculate 1 L of TB (containing 100 mg of ampicillin, 20 mg of hemin, and 0.2% (w/v) glucose) and was grown at 37 $^\circ\text{C}$ until the OD₆₀₀ reached \sim 0.6. IPTG was added (100 μM final concentration), and the cultures were then transferred to an 18 $^\circ\text{C}$ incubator and grown for 24 h. Cells were harvested by spinning the cultures at 4300 g for 20 min, and the resultant pellets were snap-frozen in liquid nitrogen and stored at -80 $^\circ\text{C}$.

For anaerobic protein expression to obtain the apoprotein, a starter culture was prepared in a serum bottle containing 60 mL of TB,

Scheme 1. Synthesis of Free-Base Corrole H₃-2 and Subsequent Phosphorus Insertion to Yield P-2

supplemented with ampicillin (100 $\mu\text{g}/\text{mL}$) and 0.2% (w/v) glucose, and then inoculated directly from a frozen RP523 glycerol stock. The bottle was sealed with a rubber septum and purged with Ar for 1 h, and then grown at 37 $^{\circ}\text{C}$ for at least 20 h. A freshly autoclaved 10 L fermenter⁶⁰ was charged with 7 L of hot, sterilized TB and 1 L of hot, sterilized H₂O (to account for the ~ 1 L volume loss due to overnight purging). After cooling to 37 $^{\circ}\text{C}$, 2 mL of antifoam and 400 mg of ampicillin were added, and the mixture was sparged with N₂ overnight. The following day, ampicillin (500 mg) and glucose (0.2% (w/v) final concentration) were added to the media, which was then inoculated with the 60 mL anaerobic starter culture. The resultant culture was grown at 37 $^{\circ}\text{C}$ until the OD₆₀₀ reached ~ 0.45 and was then cooled to 18 $^{\circ}\text{C}$ prior to inducing protein expression. Once the OD₆₀₀ reached ~ 0.7 and the temperature reached 18 $^{\circ}\text{C}$, IPTG was added (100 μM final concentration) and the culture was grown at 18 $^{\circ}\text{C}$ for 24 h to obtain the apoprotein. Cells were harvested by spinning the cultures at 4300 g for 20 min, and the resultant pellets were snap-frozen in liquid nitrogen and stored at -80°C .

Cell pellets of Cs H-NOX were thawed in a water bath at room temperature, then resuspended in Buffer A (50 mM K₂HPO₄, 300 mM NaCl, 20 mM imidazole, and 5% (v/v) glycerol at pH 8.0) supplemented with 110 mM benzamidine, 0.4 mM AEBSEF, 0.1 mg/mL lysozyme, and 0.3 mg/mL DNase. Similarly, *Pa* HasA cell pellets were resuspended in Buffer B (20 mM K₂HPO₄, 250 mM NaCl, and 30 mM imidazole at pH 7.4) supplemented with 110 mM benzamidine, 0.4 mM AEBSEF, 0.1 mg/mL lysozyme, and 0.3 mg/mL DNase. For both proteins, cells were lysed using a high-pressure homogenizer (Avestin Emulsiflex-C5). In the case of Cs H-NOX, the lysate was heated in a water bath at 60 $^{\circ}\text{C}$ for 1 h. The lysate was clarified by spinning at 42,000 g, and the supernatant was loaded onto a column containing His60 resin (3 mL for 1 L aerobic cultures or 5 mL for ~ 7 L anaerobic cultures) equilibrated with Buffer A for H-NOX or Buffer B for HasA. The resin was then washed with 20 column volumes of Buffer A for H-NOX or Buffer B for HasA. The protein was then eluted with Buffer C for H-NOX (50 mM K₂HPO₄, 300 mM NaCl, 300 mM imidazole, and 5% (v/v) glycerol at pH 8.0) or Buffer D for HasA (20 mM K₂HPO₄, 250 mM NaCl, and 300 mM imidazole at pH 7.4). The eluent was collected in five, 2–3 mL fractions. The fractions were analyzed by SDS-PAGE and UV–vis absorption spectroscopy. Typically, the first fraction contained a significant amount of nucleic acids. The main protein-containing fractions were the second and third fractions. Later fractions contained little protein and typically exhibited a shoulder on the red side of the 280 nm protein absorption peak. Fractions with comparable purity were combined and then dialyzed overnight into Buffer E (20 mM K₂HPO₄, 250 mM NaCl, and 1 mM EDTA at pH 7.4) using snakeskin dialysis tubing (3500 MW cutoff). The protein was then filtered with a 0.22 μm syringe filter and stored in sterile tubes at 4 $^{\circ}\text{C}$.

Apoprotein Reconstitution. A 1 mg/mL stock solution of corrole P-3 was prepared in DMSO. An aliquot of the H-NOX or HasA protein (~ 1 mg) was diluted to 1 mL with Buffer E in a 1.7 mL microcentrifuge tube. Then, 100 μL of the P-3 corrole solution was slowly added dropwise to the protein; the tube was gently inverted after each addition of two drops of the corrole stock solution. The reaction mixture was gently rocked at room temperature for 2 h, protected from ambient light. After incubation, the reaction mixture was spun at 21,000 g for 1 min to pellet any solids. The solution was then applied to a PD-10

column (Sephadex G-25 medium), pre-equilibrated with Buffer F (20 mM TEA and 1 mM EDTA at pH 6.5). The pink eluent was collected in 1 mL fractions. In order to remove any traces of unbound P-3, the protein-containing fractions were concentrated to <1 mL (using a 5000 MW cutoff filter), and a second PD-10 column was run using Buffer F.

Physical Measurements. NMR spectra were recorded on a Bruker AVANCE 400 NMR spectrometer at the UC Berkeley College of Chemistry NMR Facility. ¹H NMR spectra were internally referenced to the residual solvent signal ($\delta = 7.26$ for CDCl₃ or $\delta = 2.50$ for DMSO-*d*₆),⁶¹ and ³¹P NMR were internally referenced to 85% H₃PO₄ ($\delta = 0$) using a capillary tube containing the standard. Mass spectra were recorded on a Finnigan LTQ FT-ICR mass spectrometer (Thermo Fisher Scientific) equipped with an electrospray ionization source in positive ion mode at the QB3/Chemistry Mass Spectrometry Facility at UC Berkeley. UV–vis absorption spectra were acquired using a Cary 300 spectrometer (Agilent) or a NanoDrop 2000C (Thermo Scientific). Steady-state emission spectra were recorded on a Horiba Scientific FluoroMax-4 spectrofluorometer. Time-resolved fluorescence was measured using a PicoQuant FluoTime 300 fluorometer and a 520 nm PicoQuant pulsed diode laser with a PDL 820 driver. Signal was collected at the emission maximum with a 2 nm bandwidth and detected using a TimeHarp 260 time-correlated single-photon counting board. Relative quantum yields of corroles in chloroform ($\eta = 1.4459$)⁶² or proteins in TEA buffer ($\eta = 1.3329$, interpolated from published data)⁶³ were calculated using Rhodamine 101 in basic EtOH ($\eta = 1.3611$)⁶² as the reference ($\Phi_{\text{ref}} = 0.96$)⁶⁴ according to the following equation:

$$\Phi_{\text{sam}} = \Phi_{\text{ref}} \left(\frac{\nabla_{\text{sam}}}{\nabla_{\text{ref}}} \right) \left(\frac{\eta_{\text{sam}}}{\eta_{\text{ref}}} \right)^2 \quad (1)$$

where ∇ is the slope of the plot of integrated fluorescence intensity versus absorbance (constructed with 5 points) and η is the refractive index of the solvent.

Computational Details. Density functional theory (DFT) calculations were performed with the hybrid functional Becke-3 parameter exchange functional^{65–67} and the Lee–Yang–Parr nonlocal correlation functional (B3LYP),⁶⁸ as implemented in the Gaussian 16, Revision A.03 software package.⁶⁹ A polarized split-valence triple- ζ basis set that includes p functions on hydrogen atoms and d functions on other atoms (i.e., the 6-311G(d,p) or 6-311G** basis set) was used. Calculations were performed with a polarizable continuum (PCM) solvation model in chloroform using a polarizable conductor calculation model (CPCM).^{70,71} Geometries were confirmed as local minima structures by calculating the Hessian matrix and ensuring that no imaginary eigenvalues were present. Excited state calculations were performed using time-dependent DFT (TD-DFT)^{72–76} with the same functionals, basis sets, and solvation details as the ground state but with the inclusion of diffuse functions on all atoms (i.e., the 6-311++G(d,p) or 6-311++G** basis set). Excited-state energies were computed for the 20 lowest singlet and triplet excited states. Optimized geometries were rendered in Gauss View 5. Simulated UV–vis spectra were generated in the program Gauss View 5 by broadening transition lines with Gaussian functions that have a half width of 0.03 eV.

RESULTS

Corrole Synthesis and Characterization. In order to prepare a corrole analog with approximately the same size and shape as the native heme cofactor, the synthesis of corrole **H₃-2** was targeted. In order to simplify the synthesis, vinyl groups were substituted for more synthetically tractable methyl groups. Although the 2,3,17,18-tetraethyl derivative of corrole **H₃-2** has previously been incorporated into heme proteins,^{58,59} smaller methyl groups would minimize the bulk of the corrole and facilitate binding in the H-NOX heme-binding pocket. The free-base corrole **H₃-2** was prepared via oxidative cyclization of the linear tetrapyrrole *a,c*-biladiene **1** (see the [Supporting Information](#) for synthesis), using *p*-chloranil as the oxidant (Scheme 1).⁷⁷ The scale of the cyclization is critical, and the highest yields (>80%) were obtained when the reaction was run on a 60 mg scale. For convenience, two parallel reactions were performed and then combined for work-up and purification.

Metallation of the free-base corrole was attempted with a variety of light main-group elements that are known to yield highly fluorescent complexes. First, gallium coordination was performed with GaCl₃ in pyridine, following literature procedures.³⁹ A stark color change from the magenta free-base to red-orange indicated the formation of the complex. Purification of **Ga-2** on silica resulted in the decomposition of the molecule to the corresponding biliverdin. Presumably, the gallium complex acted as a photosensitizer for the generation of singlet oxygen, which subsequently reacted with the corrole across the pyrrole–pyrrole linkage (Scheme S1). This reactivity is consistent with previous reports of photochemical decomposition of highly electron-rich β -octaalkyl corroles.^{78,79}

To circumvent this deleterious reactivity, the preparation of complexes with the lighter main group elements, aluminum and phosphorus, was targeted. Following published methods,⁴⁰ aluminum coordination was performed using AlMe₃ in toluene; a drastic color change was consistent with complex formation. While the primary method for purification of aluminum corroles is recrystallization, attempts to purify **Al-2** in this way resulted in the decomposition of the corrole after ~12 h. It is likely that this complex undergoes photochemical degradation akin to the gallium analog. Attempts to purify the aluminum corrole by column chromatography were unsuccessful. The compound stuck to silica, neutral alumina, and Florisil and could not be eluted with polar solvent mixtures, including 100% methanol.

It should be noted that previously reported Ga³⁹ and Al⁴⁰ complexes utilize 5,10,15-tris(pentafluorophenyl)corrole (TPFC). Since the corrole core is inherently more electron-rich than porphyrin,⁸⁰ the strongly electron-withdrawing pentafluorophenyl substituents reduce the electron density of the tetrapyrrole core. Consequently, **H₃TPFC** is highly resistant to decomposition and is one of the most stable corrole ligands.⁸¹ Conversely, **H₃-2** has electron-donating alkyl substituents, which increase the density of the corrole core. This ligand and other β -octaalkyl corroles are prone to oxidative degradation.⁷⁸

Fortunately, the phosphorus complex of corrole **2** was readily prepared via literature methods using PCl₃⁴⁴ (Scheme 1), and the compound was obtained in 77% yield. In order to enhance water solubility and enable hydrogen bonding with the Y–S–R motif in Cs H-NOX, the methyl esters were hydrolyzed under basic conditions. A biphasic mixture of the corrole ester **P-2** in THF and 3 M NaOH was refluxed overnight. Acidic workup precipitated the carboxylic acid derivative **P-3** in high yield.

The phosphorus center of **P-2** and **P-3** could exist as one of three possible species: a six-coordinate dihydroxide, a five-coordinate terminal oxo,⁸² or a five-coordinate cationic monohydroxide⁸³ (Chart 2). Mass spectrometry is consistent with the

Chart 2. Speciation of Phosphorus Corroles.

five-coordinate formulations. It should be noted that these two scenarios are indistinguishable, as [P=O] + H⁺ and [P–OH]⁺ have identical masses. The coordination number of the P(V) center can be determined by ³¹P NMR. Chemical shifts in the –90 to –100 ppm region correspond to five-coordinate species, whereas six-coordinate complexes have resonances between –180 and –200 ppm.^{37,42} **P-2** and **P-3** exhibit a single resonance at –98.76 and –97.66 ppm, respectively, confirming that both are five-coordinate species. These values are similar to the chemical shift reported for P(V)=O octaethylcorrole (OEC) (–99.40 ppm).⁸² Finally, there is no evidence of axial –OH signals in the ¹H NMR spectrum, as evidenced by the lack of signals at < –2 ppm. Together, these data indicate that **P-2** and **P-3** are best formulated as five-coordinate P=O complexes.

The electronic absorption spectra of **H₃-2**, **P-2** (Figure 2), and **P-3** (Figure S1) exhibit intense Soret (or B) bands in the near-

Figure 2. Absorption (solid lines) and emission (dashed lines) spectra of **H₃-2** (—) and **P-2** (red —) in CHCl₃. For the emission spectra, the absorbance of the samples was matched at the excitation wavelength: A(525) = 0.1000 ± 0.0003.

UV and weaker Q bands in the visible region of the spectrum (Table 1). The free-base corrole (C_s symmetry) exhibits a split Soret band, which arises from distinct *x* and *y* polarizations of this transition.⁸⁴ Out-of-plane coordination of the P=O unit renders **P-2** and **P-3** C_s symmetric. Consequently, it is expected that the phosphorus complexes would also exhibit a split Soret

band, consistent with previously reported symmetry-dependent observations.^{44,85,86} However, the splitting is poorly resolved and the spectrum is more similar to pseudo-octahedral complexes with C_{2v} symmetry⁸⁵ and is consistent with previously reported six-coordinate phosphorus corroles.^{87–89} The addition of pyridine to a CH₂Cl₂ solution of P-2 does not change the absorption spectrum (Figure S2a). Similarly, the absorption spectrum of a P-3 solution in TEA buffer does not change upon the addition of histidine (Figure S2b). This result suggests that, unlike *meso*-triaryl P=O corroles (Figure S2c,d), P-2 and P-3 do not bind nitrogenous bases and remain five-coordinate complexes.

The emission spectra of H₃-2, P-2 (Figure 2), and P-3 (Figure S1) exhibit a sharp fluorescence transition with weaker vibrational overtones at longer wavelengths. Figure 2 illustrates the emission intensity for absorbance-matched samples of H₃-2 and P-2, indicating that the emission from the free-base corrole is more intense than the phosphorus complex. Indeed, the fluorescence quantum yields for H₃-2 and P-2 are 5.9 and 3.9%, respectively (Table 2). Emission from P-3 is extremely weak in an aqueous buffer, exhibiting a quantum yield of only 1.2%. Time-resolved measurements (Figure S3) indicate that the excited-state lifetime for P-2 is extremely short (1.2 ns), whereas the lifetime of H₃-2 is considerably longer (5.7 ns), and this value is consistent with previously reported data for free-base corroles.⁹⁰ Despite the low quantum yield, P-3 exhibits a longer lifetime of 3.8 ns when fit to a monoexponential decay. We note that a biexponential decay function nominally improves the fit of the data ($\tau_1 = 1.5$ ns, 84%; $\tau_2 = 4.9$ ns, 16%), but the physical significance of this two-component fit is unclear. Using the lifetime and quantum yield, the radiative (k_r) and nonradiative (k_{nr}) rate constants can be determined using the following equation:

$$\phi = k_r \tau = \frac{k_r}{k_r + k_{nr}} \quad (2)$$

where ϕ is the fluorescence quantum yield and τ is the excited-state lifetime. While k_r is similar for H₃-2 and P-2, this value is an order of magnitude slower for P-3. Conversely, k_{nr} is similar for both H₃-2 and P-3, but this rate constant is nearly 4 times higher for P-2.

DFT Calculations. In order to gain insight into the electronic structure of the corrole complexes, DFT calculations were performed using the B3LYP functional. Ground-state geometry optimization calculations were performed for H₃-2 and P-2, both as a terminal oxo and a dihydroxide (P(OH)₂-2), using the 6-311G** basis set and a CPCM solvation model in chloroform. The structures were verified as local minima by performing frequency calculations and ensuring that there were no imaginary frequencies. The optimized structures (Figures S4–S6 and Tables S1–S3) are qualitatively similar to previously

reported corrole structures determined by X-ray crystallography.^{44,83,91,92}

Since it appears that P-2 does not bind pyridine (Figure S2), calculations were also performed for a six-coordinate complex of P-2 with an axial imidazole ligand (P(O)(Im)-2). This structure would mimic the histidine–corrole interaction in the H-NOX and HasA heme-binding pockets. As a starting point for the geometry optimization, one of the axial hydroxide ligands of P(OH)₂-2 was replaced with an imidazole ligand, while the other was converted to an oxo. Interestingly, the imidazole ligand dissociates from the phosphorus center in the optimized structure (Figure S7 and Tables S4 and S5), resulting in a long P–N distance of 4.43 Å. The presence of imidazole destabilizes the structure by 7.2 kcal/mol (relative to the five-coordinate complex and imidazole): $\Delta G_{\text{rxn}} = +7.2$ kcal/mol for P-2 + imidazole \rightarrow P(O)(Im)-2. This supports the experimental observation that P-2 does not bind nitrogenous bases, demonstrating that the phosphorus center prefers to remain 5-coordinate.

The four frontier molecular orbitals (highest occupied molecular orbital (HOMO), HOMO–1, lowest unoccupied molecular orbital (LUMO), and LUMO+1) are energetically well-separated from the rest of the orbital manifold (Figure S8 and Table S6). Based on the Gouterman four orbital model for porphyrins,^{93–95} which has also been shown to hold for corroles,^{84,96,97} it is expected that the Soret and Q bands arise due to transitions between these four frontier orbitals. To more rigorously characterize the optical properties of these corroles, TD-DFT calculations were performed using the same methods as for the geometry optimization, but with the inclusion of diffuse functions on all atoms (*i.e.*, the 6-311++G** basis set). Single-point excited-state energy calculations were performed for the 20 lowest singlet and triplet states (Tables S7–S12) of H₃-2, P-2, and P(OH)₂-2. The four lowest-energy singlet states (S₁–S₄) give rise to two Q-like and two Soret-like transitions. These states exclusively involve the four frontier orbitals, with the exception of a minor (10%) contribution to S₃ of H₃-2 that involves HOMO–2. The deviation between the calculated and experimental transitions ranges from 0.01 to 0.18 eV, although S₁ for H₃-2 deviates by 0.24 eV. Nevertheless, these differences are substantially smaller than the absolute mean error of 0.3–0.5 eV determined from TD-DFT benchmark studies on test sets of organic molecules.^{98–100}

Although the predicted transitions do not precisely align with the data, the calculated spectra (Figures S9–S11) qualitatively reflect experimental observations. The two Q bands and the two Soret bands are orthogonally polarized; this data is summarized in Tables S13–S15, which list the electronic dipole moment vectors for states S₁–S₄. This demonstrates that both the Q and B bands are split into *x* and *y* polarizations due to the low symmetry of the corrole, consistent with previous reports.⁸⁴ Calculations indicate that H₃-2 has a substantial energy

difference between the Soret transitions (202 cm^{-1}), which results in clear separation of bands (676 cm^{-1}) in the experimental spectrum. It should be noted that these TD-DFT calculations have underestimated the experimental split in the Soret transitions. Given the out-of-plane coordination of the P=O unit in **P-2**, the calculated splitting of the B_x and B_y transitions is 519 cm^{-1} , which is larger than the experimental splitting of 249 cm^{-1} . Conversely, calculations for **P(OH)₂-2** show a very small 28 cm^{-1} separation between the B_x and B_y transitions. The experimental absorption spectrum of **P-2** exhibits a poor resolution of the Soret transitions, which is more similar to the calculated UV–vis spectrum of **P(OH)₂-2** rather than the terminal oxo **P-2**.

Protein Expression. Expression-based methods were initially explored to incorporate the carboxylic acid derivative **P-3** into Cs H-NOX, as this has been a successful methodology to replace the native cofactor of heme proteins with a variety of unnatural porphyrin complexes.⁶⁰ This approach requires the RP523(DE3) strain of *E. coli*, which has a disrupted gene in the heme biosynthesis pathway and also harbors a mutation that renders the cell well permeable to heme and heme-like porphyrins (e.g., mesoporphyrin IX).¹⁰¹ High levels of artificial porphyrin incorporation are achieved by supplementing the media with the cofactor under anaerobic conditions. Given the structural similarity of the corrole analog to the native heme cofactor, an extension of this approach to prepare corrole-substituted heme proteins was reasonable.

Small-scale (1 L) anaerobic protein expression of Cs H-NOX was performed in a three-neck bottle sealed with silicone septa and the media was supplemented with 7 mg of **P-3**. Surprisingly, the bacterial cell pellet was not pink, as would be expected if the corrole diffused across the bacterial cell wall. Although the purified protein appeared colorless, a minimal amount of **P-3** was incorporated into the H-NOX, as evidenced by a small Soret band in the absorption spectrum (Figure S12). It is possible that the speciation of **P-3** is different in water than it is in organic solvents; additional charge (e.g., $[\text{P-OH}]^+$) may prevent the molecule from crossing the bacterial cell wall. The absorption spectrum of **P-3** in the buffer is pH-dependent, which likely reflects changes in the protonation state of the molecule (Figure S13); such events are more likely for a hydroxide ligand rather than an oxo.

Encouraged by the successful heme reconstitution of an sGC from *Chlamydomonas reinhardtii* to yield a functional enzyme,¹⁰² we then turned to reconstitution methods. Both *Pa* HasA and Cs H-NOX were expressed using the RP523(DE3) strain of *E. coli*. When RP523 cells are grown anaerobically, the bacteria can grow in the absence of heme, enabling apoprotein isolation. This methodology circumvents the harsh, denaturing conditions necessary to remove the heme.^{19,29} The apoprotein was isolated in moderate yield: 2 mg/L for Cs H-NOX and 5 mg/L for *Pa* HasA. While *Pa* HasA is stable for over 1 year in imidazole-free buffer at 4 °C, Cs H-NOX undergoes complete degradation over the course of several weeks at 4 °C (or several hours at room temperature), as evidenced by SDS-PAGE. If the H-NOX protein is instead stored at 4 °C in buffer containing 300 mM imidazole, then the protein remains intact for over 1 year. This observation is consistent with a contaminating metalloprotease; imidazole coordination to the active-site Zn center inhibits activity. Leveraging the thermal stability of Cs H-NOX, heat denaturation can be utilized to inactivate any protease contaminants. Although there are several thermostable (>49 °C) *E. coli* proteins, none are proteases.¹⁰³ After heating the

crude Cs H-NOX lysate at 60 °C for 1 h, the IMAC-purified protein is stable for at least 4 months in an imidazole-free buffer when stored at 4 °C. It was determined that 60 °C was the optimal temperature because the majority of *E. coli* proteins denatured at this temperature while preserving the apo H-NOX, which significantly degrades above 66 °C (Figure S14).

Conjugate Preparation and Characterization. The conditions used for protein reconstitution were surveyed using apo H-NOX. A DMSO solution of **P-3** was added dropwise to a solution of the protein, and the resultant mixture was gently rocked at room temperature for 2 h. The reconstituted protein was separated from excess corrole on a PD-10 G-25 desalting column. The eluent was collected in 1 mL fractions and analyzed by UV–vis absorption spectroscopy (Figure S15). The first fraction exhibited a split Soret band ($\sim 400\text{ nm}$) that is significantly red shifted relative to the free corrole ($\sim 380\text{ nm}$), indicating incorporation in the heme-binding pocket. Later fractions have a Soret band comparable to the corrole in buffer, suggestive of contamination from the unbound corrole. While this spectral feature does not decrease after dialyzing the sample overnight, it is readily removed by passage through a second PD-10 desalting column (Figure S16). Perhaps the excess corrole can nonspecifically bind to the H-NOX surface, if given a sufficient amount of time.

In order to optimize **P-3** incorporation in H-NOX, the effects of buffer identity and salt concentration were surveyed for the buffer used for both the reconstitution reaction and the desalting column (Figure S17). The buffer (phosphate at pH 7.4 vs TEA at pH 7.5) used for the reconstitution reaction had a nominal effect on **P-3** incorporation. The inclusion of 250 mM NaCl in the desalting buffer eliminated nonspecific binding to the protein surface, but drastically decreased the level of corrole incorporation. Next, the pH dependence of the TEA desalting buffer was examined over the 6.5–8.5 range, and it was found that **P-3** incorporation decreased monotonically with increasing pH (Figure S18). A less dramatic effect was observed for the pH dependence of the reconstitution reaction, although pH 7.5 was optimal (Figure S19). Additional experiments were performed using TEA ($\text{pK}_a = 7.8$) (Figure S20), TEA·HCl at pH 4.8 (Figure S21), and MES buffer ($\text{pK}_a = 6.1$) (Figure S22), but these conditions did not improve **P-3** incorporation.

P-3 incorporation in Cs H-NOX is maximized when the reconstitution reaction is performed in phosphate buffer at pH 7.5 and the PD-10 desalting column is run using TEA buffer at pH 6.5 (Figure S23a). These optimized conditions were then utilized to incorporate **P-3** into *Pa* HasA and led to high levels of corrole incorporation (Figure S23b). Importantly, these samples are quite stable when stored at 4 °C protected from light, resulting in nominal corrole loss after nearly 2 months (Figure S24). In the case of **P-3** H-NOX, a 13% loss of corrole was observed after 56 days, while a 5% loss was observed for **P-3** HasA after 44 days.

Figure 3a,b compares the absorption spectra of **P-3** with the H-NOX and HasA conjugates. A significant red shift of the Soret band is observed upon protein binding and the spectrum is comparable to **P-2** in CHCl_3 (Figure 2, Table 1). Another distinction in the absorption spectra of free and protein-bound **P-3** is the width of the Q(0,0) transition $\sim 560\text{ nm}$. While the full width at half maximum (fwhm) of this feature is 25 nm for **P-3**, the values are 13 and 14 nm for the H-NOX and HasA conjugates, respectively, which is similar to the 15 nm fwhm for **P-2** in CHCl_3 . These results suggest that **P-2** in CHCl_3 is a better standard for comparison than **P-3** in an aqueous buffer. Indeed,

Figure 3. (a) Absorption (solid lines) and emission (dashed lines) spectra of P-3 (—) and the H-NOX conjugate (red —) in TEA buffer at pH 6.5. (b) Absorption (solid lines) and emission (dashed lines) spectra of P-3 (—) and the HasA conjugate (blue —) in TEA buffer at pH 6.5. (c) Comparison of the absorption (solid lines) and emission (dashed lines) spectra of the H-NOX (red —) and HasA (blue —) conjugates of P-3. For the emission spectra, the absorbance of the samples was matched at the excitation wavelength: $A(520) = 0.0735 \pm 0.0005$.

the extinction coefficients for P-2 were measured in CHCl_3 because this solvent has a similar dielectric constant ($\epsilon = 4.806$)⁶² to the hydrophobic interior of proteins ($\epsilon = 6-7$).¹⁰⁴ For the H-NOX conjugate (Figure 3a), the observed Soret to protein (280 nm) ratio is 4.88. Based on the extinction coefficients of P-2 and H-NOX (and accounting for corrole absorbance at 280 nm), the expected ratio is 5.06, indicating that >96% of the protein is in the holo form. Similarly, the observed Soret to 280 nm ratio for the HasA conjugate (Figure 3b) is 5.33, which is similar to the expected ratio of 5.18. These nominal deviations from the expected value could reflect differences in the extinction coefficient in the protein environment versus organic solvent. Nevertheless, the observed ratios indicate a high extent of P-3 incorporation in both proteins.

Figure 3c compares the absorption and emission spectra of the H-NOX and HasA conjugates. The H-NOX conjugate displays a split Soret band, while the HasA conjugate displays a single transition. This result suggests that there are distinct corrole–protein interactions in HasA and H-NOX, which could account for the difference between the observed and expected Soret to 280 nm ratios. Unexpectedly, the emission intensity of the H-NOX conjugate is weak, exhibiting a signal that is 4.7

times weaker than the emission from the HasA conjugate (Figure 3c). This is more clearly illustrated in Figure 4, which compares the emission of absorbance-matched samples of P-2, P-3, as well as the protein conjugates.

Figure 4. Emission spectra of absorbance-matched samples ($A(520) = 0.0575 \pm 0.0005$) of P-3-substituted H-NOX (—), HasA (red —), and P-3 (blue —) in TEA buffer at pH 6.5, as well as P-2 (green —) in CH_2Cl_2 .

It was our expectation that conjugate formation would enhance the fluorescence intensity (and quantum yield) relative to the free corrole because binding in the heme pocket would restrict the conformational flexibility of the molecule, decreasing nonradiative deactivation of the excited state. We also expected that the fluorescence enhancement would be greater for H-NOX because hydrogen bonding of the propionate chains to the Y–S–R motif would greatly restrict the conformational flexibility of the corrole, whereas the carboxylate groups of the propionate chains are solvent exposed in HasA. Thus, we predicted that $\phi(\text{P-2}) < \phi(\text{P-3 HasA}) < \phi(\text{P-3 H-NOX})$. It should be noted that P-2 is a better comparison for the conjugates than P-3 (*vide supra*). However, we find that $\phi(\text{P-3 H-NOX}) = 2.5\% < \phi(\text{P-2}) = 3.9\% < \phi(\text{P-3 HasA}) = 7.3\%$ (Table 2), and this is corroborated by the emission spectra of Figure 4. Time-resolved measurements (Figure S25) indicate that the excited-state lifetime for the H-NOX conjugate is 1.5 ns, which is similar to that of P-2 (1.2 ns). Conversely, the lifetime of the HasA conjugate is longer (3.1 ns) and quite similar to that of P-3 (3.8 ns). As in the case of P-3, a fit of the HasA data to a biexponential decay function nominally improves the fit ($\tau_1 = 1.9$ ns, 89%; $\tau_2 = 5.0$ ns, 11%), but the physical significance of this two-component fit is unclear. Using this data and eq 2, we find that the nonradiative rate constant k_{nr} decreases upon protein conjugation: 1.2-fold decrease for H-NOX and 2.7-fold decrease for HasA (relative to P-2). While this result confirms our hypothesis, it is counter to the expectation that H-NOX would restrict the conformation of the corrole more than HasA and result in a lower k_{nr} . It should be noted that the relative intensity of the Q(0,1) vibrational shoulder (~ 620 nm) decreases upon protein binding and this feature is highly suppressed for the H-NOX conjugate. The Q(0,0) to Q(0,1) intensity ratios are as follows: 4.61 for P-3 < 5.27 for P-2 < 5.49 for HasA < 7.41 for H-NOX. This result suggests that the corrole conformation is more restricted in H-NOX than in HasA. Since the Q(0,0) to Q(0,1) intensity ratio does not align with the observed values of k_{nr} , there are likely additional factors that dictate the photophysics of these conjugates.

DISCUSSION

Phosphorus *meso*-triaryl corroles exhibit red-orange emission profiles ($\lambda_{\text{max}} > 590$ nm) with high fluorescence quantum yields ($\phi_f = 20$ –50%).^{42,44,105} We hoped to translate these favorable optical properties into a protein environment with P-3, thus generating fluorescent proteins with optical properties that are superior to traditional fluorescent proteins. However, P-2 and P-3 exhibit yellow-orange emission with a maximum at 566 nm, which is significantly blue-shifted relative to phosphorus *meso*-triaryl corroles. This observation can readily be rationalized with a qualitative molecular orbital diagram (Figure 5). The b_1

Figure 5. Qualitative molecular orbital diagram illustrating the perturbation of the four frontier orbitals for an unsubstituted corrole core upon *meso*-aryl substitution and β -alkyl substitution.

HOMO is significantly more destabilized by an electron-donating *meso*-substituent than a β -substituent because this orbital has a greater density at the *meso* positions relative to the β positions. As a result, the HOMO–LUMO gap (ΔE) for *meso*-substitution is smaller than β -substitution ($\Delta E_{\text{meso}} < \Delta E_{\beta}$), which manifests in lower energy (longer wavelength) emission for *meso*-triaryl corroles relative to β -octaalkyl corroles.

While the majority of P(V) *meso*-triaryl corroles are six-coordinate species, P-2, P-3, and other β -octaalkyl corroles are five-coordinate. It seems that the coordination number correlates with the nature of the peripheral substituents. Phosphorus triaryl corroles exhibit an equilibrium between five- and six-coordinate species, as observed by solution ^{31}P NMR. Electron-donating substituents give rise to a 1:1 mixture of five- and six-coordinate complexes, whereas electron-withdrawing groups (e.g., 4- NO_2 -phenyl, 4-CN-phenyl) yield primarily six-coordinate species.⁴² Similarly, P corroles with fluorinated aryl groups are exclusively isolated as six coordinate complexes.^{44,87} Perhaps the reduced electron density of the macrocycle increases the effective positive charge on the P center. This leads to an increase in the ionic character of the bonding situation, which could readily be offset with two anionic ligands. Conversely, β -substituted corroles with electron-donating alkyl substituents are exclusively isolated as five-coordinate species.^{82,83} Perhaps this higher electron density at the P center increases the covalent character of the bonds; this may be efficiently utilized for π -bonding to result in the isolation of terminal oxo (P=O) derivatives.

Although phosphorus complexes of β -octaalkyl corroles have been previously characterized,^{82,83} the emission properties of these molecules have not yet been reported. The fluorescence quantum yield of P-2 is unexpectedly low. This can partially be explained by the conformational flexibility of the propionate chains, which would engender molecular motions that readily deactivate the excited state. In general, six-coordinate P(OH)₂ corrole complexes exhibit higher fluorescence quantum yields than the corresponding free-base. For example, $\phi_f = 31\%$ for the

P(OH)₂ complex of TPFC,⁴⁴ whereas $\phi_f = 13\%$ for the free-base.⁹⁰ In the case of corrole 2, the free-base has a higher ϕ_f than the phosphorus complex: 5.9% versus 3.9% (Table 1). It is unlikely that the difference in substitution pattern (*meso* vs β) accounts for this observation. Indeed, the fluorescence lifetime of H₃-2 is comparable to free-base *meso*-triaryl corroles (4–6 ns),⁹⁰ and the 2–4 fold decrease in k_r likely reflects the molecular motions of the propionate chains. Since the excited-state dynamics of H₃-2 is consistent with free-base *meso*-triaryl corroles, it is expected that P-2 should behave similarly to phosphorus *meso*-triaryl corroles. The weak fluorescence and short 1.2 ns lifetime of P-2 may be due to solvent interactions that result in the formation of nonradiative decay channels. Since the excited singlet state of P(V) triaryl corroles is a potent oxidant,¹⁰⁶ charge-transfer to solvent could occur, thereby enhancing nonradiative deactivation of the excited state. If this were the case, it would be expected that this is a general phenomenon for all P(V) corroles. However, six-coordinate P corroles and related analogues exhibit longer singlet excited state lifetimes (3–4 ns).^{106–109} Alternatively, the weak fluorescence of P-2 likely reflects differences in phosphorus speciation. Five-coordinate *meso*-triaryl corroles can be obtained by treating the six-coordinate complex with TFA, and it was shown that this five-coordinate species exhibits a lower fluorescence quantum yield (27%) and shorter excited-state lifetime (1.61 ns) than the analogous six-coordinate complex ($\phi = 44\%$, $\tau = 3.01$ ns).⁹¹ The short lifetime (1.2 ns) and low quantum yield of five-coordinate P-2 are consistent with these observations. While the speciation accounts for the short lifetime, the underlying chemical explanation for this observation remains unknown.

The short lifetime (1–2 ns) of the phosphorous corrole is consistent for P-2, P-3, and the protein conjugates. Although the excited state of P-3 and the HasA conjugate exhibits biexponential kinetics, the major contribution to the fit ($\sim 85\%$) falls in this range. Despite the similarity in lifetime, the fluorescence quantum yields are quite variable, reflecting differences in the nonradiative decay of the excited state. The protein environment surrounding the corrole likely dictates the photophysical properties of P-3. Both Cs H-NOX and Pa HasA have a tyrosine residue at the heme-binding pocket; the phenol side chain is redox active, albeit at high potentials (1.46 V vs NHE).¹¹⁰ However, since P(V) corroles are potent photo-oxidants (~ 1.2 V vs Ag/AgCl or 1.4 V vs NHE),¹⁰⁶ tyrosine oxidation could contribute to the nonradiative deactivation of P-3 in the protein conjugates. Using electrochemical and spectroscopic data, the reduction potential of the singlet excited state can be estimated. Given the structural and spectral similarity of P-2 and the P(V)=O complex of OEC,⁸² it is expected that the electrochemical properties will also be similar. Using the one-electron reduction potential of PO(OEC) (–1.58 vs SCE or –1.34 V vs NHE)⁸² and the energy of the Q(0,0) transition of P-2 (2.19 V), the estimated excited-state reduction potential is 0.85 V versus NHE. Consequently, these five-coordinate phosphorus corroles are considerably weaker photo-oxidants than six-coordinate derivatives by 0.55 V. While proton-coupled electron transfer lowers the barrier for tyrosyl radical generation,¹¹⁰ it seems unlikely that this process is operative for P-3. A more likely contribution to nonradiative decay of P-3 is histidine residues in the heme-binding pocket. Amines are well-known fluorescence quenchers. Since P-3 does not bind histidine, the nitrogen lone-pair of the imidazole side chain can quench corrole fluorescence through photo-induced electron transfer. Both Cs H-NOX and Pa HasA have heme-

ligating histidine residues, which are not participating in a bonding interaction with P-3, that are sufficiently close to the corrole cofactor to quench fluorescence. These hypotheses can be tested through site-directed mutagenesis, but such experiments are beyond the scope of this study.

The absorption spectrum of P-3 in buffer is significantly different from that of the protein-bound corrole (Figure 3). Additional evidence of protein-induced changes includes a decrease in the fwhm of the Soret and Q bands, as well as the suppression of the Q(0,1) emission band. One interesting observation is the splitting of the Soret band for the H-NOX protein. Protein binding sharpens the Soret band to enable resolution of the *x* and *y* polarizations of this transition. DFT calculations demonstrate the presence of two orthogonally polarized transitions (*vide supra*), but they are rarely resolved experimentally.⁸⁴ It is likely that hydrogen bonding of the propionate chains to the Y-S-R motif in H-NOX helps to differentiate the dipole moments along the *x* and *y* axes of the corrole, enabling the resolution of the polarized Soret transitions. Conversely, HasA lacks this Y-S-R motif and the propionate chains are solvent exposed; the lack of a hydrogen-bonding partner does not enable sufficient differentiation of the *x* and *y* dipole moments, resulting in the experimental observation of a single Soret transition.

Despite the low fluorescence intensity, the emission profile is concentrated in a relatively sharp band (fwhm = 13–14 nm). This is in contrast to traditional fluorescent proteins,¹¹¹ which exhibit broad emission profiles that can span over 200 nm, as in the case of mHoneydew, mBanana, and mTangerine (Figures 6a and S26). Of the examples illustrated in Figures 6a and S26, mKO (Kusabira Orange) and mKO2 have the narrowest peak for the main emission transition (fwhm = 27–30 nm), but this is nearly twice as broad as the H-NOX and HasA conjugates. As a result, the protein conjugates of P-3 are better suited for FRET-based and ratiometric applications because the emission intensity is concentrated in a significantly smaller spectral window. This attribute results in enhanced emission intensity, despite their low fluorescence quantum yields. Figure 6b shows the emission profiles of the fluorescent proteins in Figure 6a that have been scaled to the quantum yield of the protein. In this way, the emission intensity of the proteins is directly comparable. Although the HasA conjugate exhibits an 8.5-fold lower fluorescence quantum yield than mKO2, the corrole conjugate only exhibits a 5-fold decrease in relative fluorescence intensity at the emission maximum. Similarly, the HasA conjugate exhibits only a 1.7-fold decrease in emission intensity relative to mTangerine, despite having a 4-fold lower fluorescence quantum yield. The most striking example is a comparison of the HasA conjugate and mBanana; while the quantum yield is nearly 10 times less, the emission intensity of HasA is only 4-fold lower than mBanana. Finally, the H-NOX conjugate and mHoneydew display equal emission intensity, but the HasA conjugate has a 5-fold lower quantum yield. These comparisons illustrate that, despite their low fluorescence quantum yield, the P-3 conjugates of H-NOX and HasA offer several advantages over traditional fluorescent proteins.

CONCLUSIONS

We have presented a proof-of-principle study demonstrating that fluorescent phosphorus corroles can be incorporated into the protein scaffolds of Cs H-NOX and Pa HasA. Distinctive changes in the absorption and emission spectra confirm corrole binding in the heme pocket of the proteins. Corrole emission is

Figure 6. (a) Normalized emission spectra of the P-3 conjugates and traditional fluorescent proteins that emit in a similar spectral window: P-3 H-NOX (—), P-3 HasA (red —), mBanana (yellow —), mHoneydew (green —), and mKO (blue —). Spectral data for the fluorescent proteins was obtained from the online fluorescent protein database FPbase (fpbase.org).¹¹¹ (b) Emission spectra of fluorescent proteins that is scaled by quantum yield: P-3 H-NOX ϕ = 2.5% (—), P-3 HasA ϕ = 7.3% (red —), mBanana ϕ = 70% (yellow —), mHoneydew ϕ = 12% (green —), mKO ϕ = 60% (blue —), mKO2 ϕ = 62% (violet —), and mTangerine ϕ = 30% (orange —). Quantum yield data was obtained from FPbase (fpbase.org).¹¹¹

enhanced in the HasA conjugate, while it is quenched in H-NOX, relative to the free molecule. This observation is counter to the expectation that corrole emission would be most enhanced in H-NOX because of the buried heme pocket and hydrogen bonding with the Y-S-R motif, which would limit the conformational flexibility of the corrole. Although vibrational motions are more restricted in H-NOX relative to HasA (*i.e.*, suppression of the Q(0,1) transition), the nonradiative rate constant is slower in HasA than H-HOX. This disparity suggests that environmental factors in the heme-binding pocket are playing a significant role in dictating the photophysical properties of these conjugates.

We are currently working to improve the optical properties of the conjugates by modifying both the corrole and the heme-binding pocket of the proteins. Conversion of five-coordinate P-2 to a six-coordinate species (as a difluoride (PF₂),⁴⁴ dialkyl (PR₂),⁸² or dialkoxide (P[OR]₂)^{42,89}) should enhance the fluorescence of the corrole. However, it is unclear if or how such a six-coordinate species would bind to the H-NOX and HasA proteins. Alternatively, modification of the corrole by β -fluorination or β -trifluoromethylation would reduce the electron density of the macrocycle and could enable the isolation of stable Al and Ga complexes. These derivatives are expected to exhibit more red-shifted emission profiles and higher fluorescence quantum yields than the corresponding P complex. So far, attempts to adapt the synthesis of 1 using 3,4-difluoropyrrole instead of 3,4-dimethylpyrrole have been unsuccessful. Additionally, it is unclear exactly how the corrole complex is

interacting with the protein, especially since P-2 and P-3 prefer to remain five-coordinate in the presence of a nitrogenous base (e.g., pyridine or histidine). X-ray crystal structures of the protein–corrole conjugates would aid in the structure-guided design of these unnatural cofactors. With a detailed understanding of the corrole–protein interaction, selected variants can be generated to enhance the optical properties of these fluorescent proteins. Together, modification of the corrole cofactor and heme-binding pocket of the protein will result in enhanced conjugates with higher fluorescent quantum yields.
