Metal–ketene complexes¹ have been suggested as intermediates in reductions of CO and CO₂ in industrially important processes.² Ketene complexes have been implicated as crucial intermediates in thermal reactions (e.g., the Dötz reaction)³ and in photoinduced transformations of Fischer carbene complexes, although in the latter case such species have yet to be detected spectroscopically or isolated.⁴ Side products in both thermal and photochemical reactions of Fischer carbene complexes suggest that intramolecular C–H bond activation of either carbene or ketene intermediates is possible,⁵ but this has not been demonstrated on an isolable ketene complex.¹ Here we report that structurally characterized Ir–ketene complexes **1**⁶ undergo C–H bond activation both thermally and photochemically. Quantitative photochemical conversion of **1** at –25 °C to a *cis*-aryl(hydride)Ir(III) complex **2** is cleanly reversed at ambient temperature. A net 1,3-hydride shift (**1** → five-coordinate acyl **5**) is shown to be the result of a four-step *hydride walk*, by way of **2**, **3**, and **4** (Scheme 1). The last intermediate (**4**) is a five-coordinate enol complex which, like its acyl tautomer **5**, adds CO stereoselectively.

Complex **1a**⁶ could be produced by direct complexation to Ph₂C=C=O⁷ (88% after chromatography over SiO₂). Heating a solution of **1a** in C₆D₆ (80–90 °C, 8–9 h) led to **5a** in 88–92% yield. The ¹H NMR spectrum of **5a**⁸ showed resonances for nine aromatic protons, a one-proton singlet at δ 4.52, and absorptions for two P(*i*-Pr)₃ ligands. In the ³¹P{¹H} NMR spectrum, an AB pattern with large coupling (313.3 Hz) indicated inequivalent, mutually *trans* phosphines. In the ¹³C spectrum (C₆D₆), only two triplets were seen, at δ 195.92 (*J* = 3.2 Hz) and 139.03 (*J* = 7.0 Hz), supporting the assignment of an acyl carbon and an aryl carbon bound to the IrCl[P(*i*-Pr)₃]₂ unit. Save for the lack of observable coupling to the proton resonating at δ 4.52 ppm, these data might be consistent with

Scheme 1^a

rise to a mixture containing products **5a** (6%), the known *trans*-(CO)IrCl[P(*i*-Pr)₃]₂ (11%),^{13,14} and **4a** (78%, versus internal standard). The new complex **4a** bears equivalent ³¹P nuclei, and its ¹H NMR spectrum showed resonances for nine aromatic protons as in **2a** or **5a**, but in addition, a sharp one-proton singlet at 7.07 ppm, which disappeared on shaking with D₂O.^{15a} Moreover, **4a** exhibited a weak, broad IR absorption near 3350 cm⁻¹, as seen in spectra of organic enols,^{15b} and this shifted to 2470 cm⁻¹ on exchange with D₂O. ¹³C NMR and HMBC data for **4a** indicated that the resonances for the HOC=C unit appeared at δ 150.07 (t, *J* = 6.5 Hz, C1) and 127.29 (t, *J* $\approx$ 1 Hz, C2). The spectral evidence in favor of an enol formulation was corroborated by tautomerization of **4a** to **5a** on standing in solution in the dark (half-life ca. 15 h) or on attempted chromatography over silica gel. Similarly, **4a-O-d** isomerized to **5a-C2-d** over 1 day. Control experiments were undertaken to characterize the prototropy in **4a** and **5a**. In the dark, **5a** showed no evidence¹⁶ of deuteration at C2 after 2 days with D₂O at 30 °C, or after 8 h at 80 °C. Addition of DCl (0.25 equiv) to the mixture resulted in 60% deuteration of **5a** at C2 after 2 h at 80 °C (with some decomposition). Irradiation of **5a** did not lead to **4a**, and irradiation in the presence of D₂O (5 h) did not give rise to detectable deuteration at C2.^{15c,16} Furthermore, the alcohol function in **4a** could be trapped quantitatively with Ph₂C=C=O^{1c} to give chelate **7**, with a red-shifted IR absorption for the ester carbonyl of 1630 cm⁻¹.¹⁷

Further studies involving ligand additions to **4a** and **5a** gave a clearer picture of the bonding and reactivity of these ketene-derived species. Bubbling CO into a solution of **5a** for 2 min produced a mixture of diastereomeric, chromatographically separable adducts **8** and **9** in a ratio of 4:1 (Scheme 1).¹⁸ Similar treatment of enol **4a** with CO gave the adducts **10** and **11** (eq 1, ratio 3.5:1), each exhibiting a sharp singlet for the enolic proton at δ 8.33 and 5.95, respectively.^{15a,19} Significantly, the

isomeric enols showed very different chemical behavior. First, on saturating the solution of **10** and **11** with D₂O at room temperature, the O–H signal of the minor adduct **11** disappeared at least 100 times more rapidly than that of the major isomer **10**: times for completion were $\leq$ 5 min for **11** and 0.5 days for

10. Second, whereas **11** tautomerized to **9** on silica gel, **10** could be isolated unchanged in 58% overall yield from **1a**. The far greater stability of **10**²⁰ and the downfield shift of its hydroxylic proton are both attributed to an intramolecular hydrogen bond^{21ab} which based on these two criteria must be stronger in **10** than that in the five-coordinate **4a**.

We have been unable to detect **3** (Scheme 1), but it is a reasonable link between **2** and **4**: isomerization of **2a** could lead to **3a**.²² From **3a**, enol **4a** could be produced by insertion of the ketene C=O function into the Ir–H bond. In contrast, insertion of the C=C bond into M–H bonds was reported in two intermolecular reactions,²³ where the geometric constraints of the intramolecular reaction **3** $\rightarrow$ **4** were absent. From the evidence gathered to date, the ketene functionalization represented by isomerization of **1a** to **5a** occurs by way of a four-step hydride walk, instead of by direct 1,3-hydride shift.²⁴

Despite the importance of acyl ligands, and studies in the last decade on their deprotonation (usually with strong bases),²⁵ the chemistry of tautomeric enol complexes involving σ -bound metal substituents²¹ is virtually unexplored. The results here demonstrate for the first time in high-yield^{1,9} reactions on isolable species that ketene complexes can be a source of enol and acyl²⁶ ligands through thermal or photochemical C–H bond activation and subsequent hydride walk.

Acknowledgment. We thank the donors to Petroleum Research Fund, administered by the ACS, for partial support of this work and Johnson Matthey Aesar Alfa for a loan of iridium salts and Cambridge Isotope Labs for a grant of ¹³CO. Dr. Ron Nieman and Camil Joubran assisted with vital 2D NMR experiments.

Supporting Information Available: Spectral data and preparations of 15 compounds (22 pages). This material is contained in many libraries on microfiche, immediately follows this article in the microfilm edition of this journal, can be ordered from the ACS, and can be downloaded from the Internet; see any current masthead page for ordering information and Internet access instructions.

(20) In solution, pure **10** was consumed very slowly ($\sim$ 2% per day), forming **9**, whereas **11** (as a mixture with **10**) isomerized to **9** with a half-life of about a day.

Soc.* **1991**, *113*, 4530–4544. (c) Many π -complexes of enols are known: see over 20 references in footnote 5 of ref 21b.

(22) Addition of P(*i*-Pr)₃ (3 equiv) did not slow the conversion of **1a** to **4a**. Possible routes from **2** to **3** and **4** could involve dissociation of the ketene C=O bond, or P(*i*-Pr)₃, or chloride, but present data do not allow us to distinguish rigorously between these possibilities. An intramolecular rearrangement is suggested by the observation that changing the initial concentration of **1a** by a factor of 2.8 did not change the time required to consume 90% of **1a**, and disappearance of **1a** followed first-order kinetics. We thank a reviewer for suggesting bimolecular pathways from **2** to **3**, or chloride dissociation, but the latter seems unlikely in benzene or toluene solvent.

(24) (a) It is not known if alternative isomerization of **1** to an undetected η^2 -(C,C)-bound isomer, followed by metalation at an ortho position, leads to **2**, **4**, and **5**. If metalation occurred on a C,C-bound isomer of **1**, then both **1b** and **1c** would provide the same mixture of isomeric metalation products. However, at -25 °C metalation of **1b,c** to **2b,c** is completely regiospecific. At the higher temperatures used to form **4a**, mixtures of products result from irradiation of **1b,c**, from equilibration between **1b,c** (dark reaction, 25 °C, half-life ca. 14 days; 70 °C, complete in 1 h), which is greatly accelerated on irradiation (28–30 °C, complete in 3 h). Further experiments to determine whether the metal moves by way of η^2 -(C,C) or η^1 -O isomers will be necessary,^{24b} but based on steric considerations alone, the latter possibility is preferred. (16) Estimated lower limit of detection is 10%.

(17) For a similar observation in a crystallographically characterized chelate, see: Esteruelas, M. A.; Lahoz, F. J.; López, A. M.; Oñate, E.; Oro, L. A. *Organometallics* **1994**, *13*, 1669–1678.

(18) Key ¹³C NMR data: for **8** (C₆D₆), δ 234.95 (t, *J* = 8.1 Hz, acyl C), 180.67 (t, *J* = 9.3 Hz, CO); for **9**, δ 214.03 (t, *J* = 4.5 Hz, acyl C), 177.77 (t, *J* = 9.1 Hz, CO). IR for **8**: 2004 (CO), 1665 (acyl) cm⁻¹. IR for **9**: 2023 (CO), 1640 (acyl) cm⁻¹. Assignments were fully corroborated by labeling with ¹³CO.^{8,19} At room temperature in solution, **8** isomerized to **9** (half-life ca. 30 h).

(19) ¹³CO was added to **5a** or **4a**, giving the ¹³CO isotopomers of **8-11**. Chelate **7** opened to a single adduct, in which the ¹³CO and phenyl ligands were *trans*. Typical values for ²*J*_{CC} across Ir in these complexes for *trans*- and *cis*-disposed carbons were 30.8–36.8 and 1.5–2.0 Hz, respectively.⁸ The enolic proton resonance in the spectrum of **10-¹³CO** appeared as a doublet (*J* = 1.8 Hz).
