A small library of *N,N*-diethyl- and -diethanolsulfonamides of differently substituted 2-(2-pyridyl)- and 2-pyrazinyl-4-alkoxythiazoles has been synthesized and investigated in terms of their photophysical properties, electronic structure (quantum chemical calculations at the CAM-B3LYP/6-31+G(d,p) level of theory) and thin film morphology (Langmuir-Blodgett- and spin-cast films). By using the Langmuir-Blodgett technique we show how to exert direct control over the degree of aggregation in thin films made from different thiazole type dyes. In combination with spectroscopic investigations, we gained an in-depth understanding of the influence of aggregation on the electro optical properties of thin films made of the here investigated substances.

### Introduction

The 4-hydroxy-1,3-thiazole chromophore and fluorophore is structurally very similar to the naturally occurring firefly luciferin, thus possessing remarkable spectroscopic characteristics.<sup>1, 2</sup> The classical heterocyclic hydroxythiazole core was described by Chabrier *et al.* in 1949,<sup>3</sup> although the thiazolin-4-one structure, the keto-tautomer of the hydroxythiazole, had been proposed at that time and was later proven to be the enol form.<sup>4</sup> In the following years, 4-hydroxy-1,3-thiazoles have been tested for only few applications in biochemistry, e.g. as inhibitors for several enzymes such as cyclooxygenase, 5-lipoxygenase and cyclin-dependent kinase 5.<sup>4-6</sup> During this period, their ability to fluoresce upon photoexcitation was never mentioned. Since the revival of intense scientific investigation on this substance class in 2007,<sup>1</sup> several applications of its derivatives have been developed. Very recently a new derivative has been utilized as a reporter molecule for fluorescence and mass spectrometric detection of a model protein.<sup>7</sup> Furthermore, they have been reported to

be fast and specific systems for fluoride ion detection.<sup>8</sup> Recent research indicates that thiazole-based fluorophores, due to their matching excitation and emission characteristics, are potential sensitizers for the highly efficient chemiluminescence of the 2-coumaranones.<sup>9-11</sup> 4-Hydroxythiazole derivatives have furthermore been employed as light-harvesting ligands in Ru<sup>II</sup> polypyridyl complexes.<sup>12</sup> Thanks to their easy functionalization and tunable optical properties they have been successfully incorporated as blue-emitting species in polymer backbones,<sup>13, 14</sup> as a Förster resonance energy transfer (FRET) energy donor in a terpolymer alongside a Ru<sup>II</sup> complex as the acceptor unit,<sup>15</sup> and as chromophores in donor- $\pi$ -acceptor (D- $\pi$ -A) dyes in dye-sensitized solar cells (DSSCs).<sup>16</sup> It was shown that in DSSCs aggregation of thiazoles reduces the DSSCs performance.<sup>16</sup> Recent approaches to avoid dye aggregation by introduction of atomic spacers and side chains yielded dramatically increased DSSC efficiencies.<sup>17-21</sup> Beyond this already successful approach of aggregation inhibition, different methods of directed self assembly and aggregation, such as the formation of hydrogen bonds and/or  $\pi$ - $\pi$ -stacking interactions have shown to be promising approaches for improving the efficiency of optoelectronic and photovoltaic devices.<sup>22-27</sup>

We aim for controlling the formation of supramolecular architectures to be used in photon conversion.<sup>28-33</sup> For this purpose, we utilize self-assembly of amphiphilic molecules, especially at interfaces.<sup>34-41</sup> In the present study we developed amphiphilic hydroxythiazole derivatives by attaching both hydrophilic groups and non-polar chains to the fluorophore: a series of *N,N*-dialkylsulfonamide substituted 4-alkoxy-1,3-thiazoles has been synthesized. These compounds can be tuned in their hydrophilicity, which generally opens up opportunities for novel applications, e.g. in biomedicine<sup>42-44</sup> or pharmacy.<sup>45-47</sup>

## ARTICLE

Journal Name

The new compounds bear either a 2-pyridyl- or a pyrazinyl-substituent in 2-position, different alkoxy groups in 4-position and a *p*-sulfonamide substituted phenyl ring in 5-position. Both *N,N*-diethyl- and *N,N*-diethanolsulfonamide derivatives have been prepared from each building block. 2-Pyridyl-substituents in 2-position facilitate high quantum yields,<sup>1</sup> pyrazinyl rings were introduced to manipulate electronic features of the compounds.<sup>48</sup> In this paper we present both the synthesis as well as the characterization of the novel thiazoles with a particular focus on the spectroscopic properties and possible surface activity. Photophysical properties of the new sulfonamide containing fluorophores are supplemented by quantum chemical studies.

## Results and Discussion

## Synthesis

Preparation of the starting material **1** followed a straightforward synthesis based on *Hantzsch* cyclization between 2-bromo-2-phenylethylacetate and pyridine-2-carbithioamide. Synthetic procedures can be found in the literature.<sup>8, 12, 15</sup> The *O*-alkylated derivatives **2a-c** were obtained in very good yields by simple *Williamson* type etherification. They were then treated with neat chlorosulfonic acid in order to obtain the sulfochlorides **3a-c** (84-91% yield). If the reaction was carried out in chloroform, no conversion of the starting materials was observed. The reaction of **3a-c** with diethylamine or diethanolamine yielded new sulfonamides **4a-c** and **5a-c**, respectively, in 77-89% yield (Scheme 1, top). Derivatives **4a** and **5a**, both of which are bearing a methyl ester function, can be further transformed to the corresponding carboxylic acids **6**, **7** (Scheme 1, bottom). Saponification was performed with KOH in aqueous ethanol and the corresponding carboxylic acid was precipitated with dilute HCl. **6** and **7** are soluble in alkaline aqueous solutions.

Compounds that are structurally similar to **4-7** but bearing a pyrazine ring in 2-position of the thiazole were prepared following the same synthetic procedures as applied to obtain **4-7**. A synthetic protocol for the preparation of the starting material **8** (see Scheme 1, middle) can be found in the literature.<sup>48</sup> Hydroxythiazole **8** was subsequently alkylated with methyl bromoacetate, 1-bromo-3-chloropropane or methyl iodide to obtain the ethers **9a-c**. Chlorosulfonation of **9** and treatment with diethylamine or diethanolamine afforded the sulfonamides **11a-c** and **12a-c** in good to very good yields (Scheme 1, middle). The methyl ester in both **11a** and **12a** were cleaved to **13,14** using KOH in aqueous ethanol (Scheme 1, bottom), analogous to the preparation of **6** and **7**.

Chemical structures of the new compounds were confirmed by means of NMR, MS, high resolution MS and UV/Vis spectra. Sulfochlorides **3a-c** and **10a-c** have only been characterized by NMR and MS and were rapidly converted to the corresponding sulfonamides, as they were highly sensitive to humidity. Even if stored in a closed flask in the freezer overnight, isolated yields decreased significantly. It is also noteworthy that none of the sulfochlorides exhibited fluorescence emission, neither in

solution nor in the solid state, most likely due to intersystem crossing to the triplet manifold *via* spin-orbit-coupling.<sup>49–51</sup> The contrary is the case for alkoxy thiazoles **2a–c** and **9a–c**, the corresponding sulfonamides **4a–c**, **5a–c**, **11a–c**, **12a–c** and carboxylic acids **6**, **7**, **13** and **14**. All of these show fluorescence both in the solid state and in solution (*vide infra*), although containing one or more sulfur atoms each, which can promote intersystem crossing to the triplet manifold as mentioned above.

### X-Ray Crystal Structures

X-ray crystallographic analysis was performed to confirm successful synthesis of the target compounds, to characterize the molecular geometry, as well as to investigate intermolecular interactions. Single crystals suitable for X-ray structure analysis were obtained from slow diffusion of pentane into a saturated solution of **4c** in EtOAc. The crystal structure of **4c** is depicted in Figure 1. It reveals the almost planar arrangement of the compound. The torsion angles between the three aromatic rings are 3.6(2)° (C4–C5–C6–N2) and 7.8(2)° (C7–C8–C9–C14). The methoxy group is twisted only 6.68(19)° out of plane (C15–O1–C7–N2). While S2 is in plane with the aromatic ring it is attached to (S2–C12–C13–C14: 178.42(11)°), the sulfonamide-nitrogen N3 is distinctly tilted towards the phenyl ring (N3–S2–C12: 109.17(6)°). A look at the molecular packaging of **4c** reveals that the molecules are not arranged parallelly due to the steric demand of the ethyl groups on the sulfonamide moiety. Therefore no  $\pi$ -stacking is present in the single crystals. Instead, the molecules are arranged in zigzag like stacks where the orientation of the molecule is alternating. The distance between two similar

atoms in parallelly arranged molecules is 8.2(6) Å (see also: Fig.S1–S3, ESI), indicating no  $\pi$ - $\pi$ -stacking interactions in the crystalline state.<sup>52, 53</sup>

Single Crystals of **11a** that were suitable for X-ray structure analysis were obtained by slow evaporation of a concentrated solution of **11a** in EtOAc. The crystal structure is depicted in Figure 2. Expectedly, the three aromatic rings form a co-planar structure. The pyrazine ring in 2-position of the thiazole core is twisted 2.17(2)° out of plane (N1–C1–C17–N4: 177.83(12)°) and the sulfonamide containing phenyl ring is twisted 7.51(2)° (C2–C3–C4–C5: 172.49(14)°) with regard to the center ring. The glycolic ester moiety is also in plane with the aromatic fluorophore system (C1–N1–C2–O3: 178.81(11)°, C2–O3–C14–C15: 177.90(11)°, C16–O5–C15–C14: -178.33(12)°, C16–O5–C15–O4: 2.7(2)°). Only the sulfonamide moiety, due to the sp<sup>3</sup> hybridised S2, is significantly tilted towards the phenyl ring in 5-position of the thiazole (N2–S2–C7: 107.78(6)°). In the crystal, the molecules are arranged in stacks where the thiazole cores are located on top of one another and the pyrazine ring of one molecule slightly overlaps with the phenyl ring of another (Fig. S4, ESI). The sulfonamide moieties are tilted towards the next molecule in the stack. The distance between the thiazole cores in the different layers is 3.3(3) Å (see Figure 2), thus indicating  $\pi$ - $\pi$ -stacking interactions in the crystalline state,<sup>52, 53</sup> probably occurring due to the minimization of the overall dipole moment through anti-aligned dipoles.<sup>54, 55</sup>

## Optical Properties

Spectroscopic data (UV/Vis and fluorescence) for **2a-c**, **4a-c**, **6** and **7** are summarized in Table 1. Since all UV/Vis spectra look very similar, only one example (**6**) is shown in Figure 3. The same is the case for fluorescence emission spectra. All other spectra can be found in the ESI (Fig. S5-S14).

The absorption spectra of all compounds exhibit a single structureless band with maxima between 372 and 378 nm, which can be assigned to  $S_0 \rightarrow S_1$  transitions. Values for  $\epsilon$  range from  $2.05$  to  $3.02 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ . A second, shorter-wavelength absorption band was observed for **2a-c**, **4a-c** and **6**. Only in **2a**, **4a** and **6** those bands were distinctly separate and their maxima are 270, 284 and 285 nm, respectively. They can be assigned to  $S_0 \rightarrow S_2$  transitions. The emission maxima range from 440 to 447 nm. Stokes shifts are very similar for all compounds and range from  $4084$  to  $4287 \text{ cm}^{-1}$  (0.50-0.53 eV). This is in good agreement with previous observations for similar compounds.<sup>12,15</sup> The fluorescence quantum yields of **2a-c** are 0.85, 0.81 and 0.75, respectively, i.e. they decrease from **2a** to **2c**. No such trend was observed for diethyl sulfonamides **4a-c** ( $\Phi_F = 0.80$ -0.83) and diethanol sulfonamides **5a-c** ( $\Phi_F = 0.77$ -0.79). Quantum yields for carboxylic acids **6** and **7** are 0.75 and 0.71, respectively and are therefore slightly lower than all others. Overall it can be said that good to very good quantum yields were achieved for **2a-7**. It is also worth mentioning, that the introduction of sulfonamide moieties did not significantly decrease fluorescence quantum yields.

Spectroscopic data (UV/Vis and fluorescence) for **9a-c** and **11a-14** are summarized in Table 1. The absorption spectra of all compounds exhibit a single structureless band with maxima between 385 and 391 nm, which can be assigned to  $S_0 \rightarrow S_1$  transitions. Values for  $\epsilon$  range from  $2.15$  to  $2.85 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ . A second, shorter-wavelength absorption band was observed for all pyrazine derivatives. It can be assigned to  $S_0 \rightarrow S_2$  transitions. The maxima range from 274 to 277 nm for **9a-c** and from 286 to 289 nm for **11a-14** (see ESI). All compounds **9a-14** exhibit two emission maxima between 453 and 470 nm. It is noteworthy that for the esters **9a**, **11a** and **12a**, the shorter-wavelength emission band is

Figure 3 UV/Vis absorption (dashed) and fluorescence emission (solid) spectra of **6**,  $2 \times 10^{-6} \text{ M}$  in THF.

Figure 4 UV/Vis absorption (dashed) and fluorescence emission (solid) spectra of **11a**,  $2 \times 10^{-6} \text{ M}$  in THF.

slightly more intense than the longer wavelength signal. The opposite is the case for **9b,c**, **11b,c**, **12b,c**, **13** and **14**. The UV/Vis absorption and fluorescence emission spectra of **11a** are depicted in Figure 4. All other spectra can be found in the ESI (Fig. S15-S23). Stokes Shifts are between  $3899$  and  $4654 \text{ cm}^{-1}$  (0.48-0.58 eV). Fluorescence quantum yields are very similar for **9a-12c**: they range from 0.72-0.79. Only the carboxylic acids **13** and **14** feature a slightly lower quantum yield of 0.67. As for the pyridyl derivatives, good fluorescence quantum yields were achieved for the pyrazine compounds. The introduction of sulfonamide moieties did not significantly decrease quantum yields and only those of carboxylic acids are slightly lower than all others.

## Electronic Structure Calculations

To gain a more detailed insight in the emission and absorption properties of the here presented sulfonamide substituted 4-alkoxy-1,3-thiazoles, we applied density functional theory (DFT) and time dependent density functional theory (TD-DFT) to those derivatives of interest (**4a-c**, **5a-c**, **6**, **7**, **11a-c**, **12a-c**, **13**, **14**). The effect of solvation (THF) was addressed by means of the polarizable continuum model<sup>56</sup> as implemented in Gaussian 09.<sup>57</sup>

The frontier orbitals of **4a** and **11a** are depicted in Figure 5 as illustrative examples. Both HOMOs and LUMOs are mainly delocalized over the whole molecule with exception of the glycolic ether in 4-position of the thiazole core and the ethyl groups of the sulfonamides. Therefore the MO constructs suggest a significant overlap of the HOMO and the LUMO for the molecules. This observation nicely corresponds with the high experimental extinction coefficients and is also reflected in high theoretical oscillator strengths (*vide infra*) and their highly efficient fluorescence.

Moreover Figure 5 clearly shows that the HOMO- and LUMO-shapes of both compounds **4a** and **11a** are virtually identical. Considering that all calculated absorption and emission properties are only involving these frontier orbitals, this may serve as a possible explanation for the quite small gap between the absorption and emission maxima of pyridyl and

All measurements were performed at r.t. Quinine sulfate was used as standard for the determination of quantum yields ( $\Phi = 0.52$ ).

**Figure 5** Frontier Orbitals (HOMO, LUMO) of **4a** and **11a**, optimized at the CAM-B3LYP/6-31+G(d,p) level of theory.

pyrazinyl derivatives (see Table 3).

The calculated absorption and emission maxima are in a good agreement with the experimental values. Nonetheless, it must be said that the calculated absorption wavelengths entail a larger error (0.19–0.29 eV) than the calculated emission wavelengths (0.03–0.11 eV). Yet the error is always within the 0.3 eV margin that is typical for TD-DFT calculations<sup>58, 59</sup> and especially for thiazole-based chromophores like firefly oxyluciferin.<sup>60</sup>

The UV/Vis-absorption as well as the emission properties of the studied molecules only consists of transitions from the HOMO to the LUMO (or *vice versa*). It is noteworthy that all of the here studied derivatives feature very high oscillator strengths for their  $S_0 \rightarrow S_1$  transition (0.9180 - 0.9906).

As can be seen in Table 3, the Stokes shifts for all sulfonamide compound can also be calculated within a reasonable margin of error (0.14 – 0.20 eV). All theoretical Stokes shifts are overestimating the experimental value by a mean of 0.16 eV. Since this offset has a very low standard deviation (0.02 eV), the calculated Stokes shift can be corrected by the empirical value of 0.16 eV to give a much smaller discrepancy in comparison with the experimentally determined values (-0.03

### Solubility and Surface Activity

To utilize the amphiphilicity of the thiazoles and the resulting self-assembly at the air-water interface we applied the Langmuir-Blodgett (LB) technique for assembling and deposition of the dyes.<sup>36, 61-64</sup> For this purpose the thiazoles were dissolved in a volatile solvent (typically chloroform), the resulting solution was carefully dispersed on the water surface of the LB-trough and the LB-experiments were started after solvent evaporation. The LB-isotherms of **4a-c**, **5a-c**, **6**, **7**, **11a-c**, **12a-c**, **13** and **14** were recorded at a constant compression speed of 375 mm<sup>2</sup>/min. Under these conditions the compounds **6**, **12c** and **13** did not show any resistance to compression on the LB-trough which suggests that they are getting dissolved in the water subphase. Substance **14** is not soluble in organic solvents and was therefore not tested, thus we are discussing only the derivatives of types **4**, **5**, **11** and **12** in the following.

Figure 6 depicts the isotherms of **4a-c** and **11a-c**. The isotherms of **5a-c**, **7** and **12a,b** can be found in the ESI (Fig. S24). The corresponding values for collapse area ( $A_c$ ) and pressures ( $\pi_c$ ) are shown in Table 4. The collapsing point here is defined as the inflexion point of the isotherm<sup>39</sup> that is generated by a pressure-induced phase- transition.<sup>65</sup> The third parameter that is considered to compare the isotherms to each other is  $A_{\text{ext}}$ , which is the hypothetical area per molecule of the liquid phase at a surface pressure of 0 mN/m (see Figure 6). An exemplary fit of the linear region of the graph that was used for the determination of  $A_{\text{ext}}$  is depicted in Figure 6 for **4b**.

**Figure 6** LB-isotherms of **4a-c** and **11a-c**, recorded with a constant barrier speed of 5 mm/min. For the measurement a volume of 50  $\mu$ L was spread on the trough (concentrations are presented in Table 4). An exemplary linear fit is shown for **4b**.

The isotherms of **5a-c**, **7**, **12a** and **b** exhibit an almost linear curve progression at high surface-pressure and no signs of phase transition (Figure 6). Moreover, their  $A_{\text{ext}}$  value is already very low before the compression starts (around  $25 \text{ \AA}^2$ ). The same LB-behavior is found for Lauric acid and is explained by its slight solubility in water.<sup>61</sup> We therefore assume that **5a-c**, **7**, and **12a,b** are also slightly water soluble. This seems reasonable due to the two hydroxyl-groups on the sulfonamide moiety which increase the hydrophilic properties. **4a-c** show a sharp collapse-point at relatively low pressures (12 - 15 mN/m, see Figure 6 and Table 4). This indicates a typical phase-transition as observed for many long-chain amphiphiles.<sup>61</sup> As opposed to **4a-c**, isotherms of **11a-c** show several weak points of inflection, particularly **11b**, and their collapse pressures are significantly and systematically higher, while the only molecular structural difference to **4** is the replacement of the pyridyl moiety by the pyrazinyl ring. A very dense packing in the Langmuir monolayers in the trough is observed for derivatives **5**, **7**, **12** that have alcohols attached to the sulfonamide group to make it even more polar. Thus the polar heads provide a strong hydrophilic anchor, which causes small molecular areas in the dense Langmuir films of about  $20 \text{ \AA}^2$  as shown in Table 4. In contrast, derivatives of types **4** and **11**, which are bearing short alkyl chains instead of alcohols attached to the sulfonamide, are showing significantly larger molecular areas ranging from 40 to  $70 \text{ \AA}^2$  because of the weaker hydrophilic anchor. Additionally, the molecular areas of **4a-c** and **11a-c** depend on the substituents introduced at the 4-hydroxy-group of the thiazole. Expectedly, a- and b-type substitutions induce stronger interactions of the chromophores with the subphase as compared to the methyl-(c)-substitution, thus causing generally somehow larger molecular areas. Remarkably, the molecular area of **4b** is exceptionally large ( $A_c = 70 \text{ \AA}^2$  and  $A_{\text{ext}} = 74 \text{ \AA}^2$ ) and indicates a flat orientation of **4** at the water surface (largest molecular spatial demand on a flat surface approximately  $5 \text{ \AA} \times 14 \text{ \AA} \approx 70 \text{ \AA}^2$ ).

**Table 4** Concentrations of the spread solutions and calculated collapse parameters of the LB-isotherms.

$A_{\text{ext}}$ , value of the area per molecule at the theoretical pressure of  $\pi = 0$ ;  $A_c$  and  $\pi_c$ , values of the area per molecule and the pressure at the collapse-point of the isotherm.

As discussed qualitatively above, the most obvious polar anchors of the chromophores are the sulfonamide groups highlighted by green ellipsoids in Figure 7. To estimate the possible weight of further polar moieties we computed the electrostatic potential at the van-der-Waals surface as a sum over contributions due to partial charges at every atomic site (see Figure 7). Partial charges have been partitioned using the MMFF94<sup>66</sup> force field after quantum chemical optimizations considering polarizable continuums as artificial environment. In each case, the methyl ester group is pointing away from the rest of the molecule, an unlikely conformation for a single molecule at an air water interface. Instead, the methyl ester group will most likely bend into the water phase. However, possible anchor groups at the interface can clearly be identified by their high polarity in decreasing order of anchoring strength from Figure 7: methyl esters, sulfuryl moieties, hydroxyethyl groups, pyrazinyl and pyridyl rings. Figure 7 reveals that, additionally to the sulfuryl moiety, the methyl ester and the pyrazinyl/pyridyl rings show considerable polarity. Therefore, **4a** and **11a** appear likely to be anchored with one long side of the chromophore on the water surface, thus explaining the medium sized experimentally determined molecular areas of 44 and 62 Å<sup>2</sup>, respectively. As can be seen in Figure 9, the pyrazinyl ring in **11** exhibits a lower dipole moment making it a slightly worse anchor as compared to the pyridinyl-ring in **4**, thus allowing **11** to leave the flat orientation at lower surface pressures than substances **4**. Considering the fact that substances of type **11** stack well in the solid state (see Figure 2), in contrast to substances **4**, we conclude that substances of type **11** gradually move into an upright orientation as the surface pressure increases. Substances of type **4**, however, cannot stack in such an upright orientation causing the highly ordered structure to break down completely at a certain well-defined surface pressure. Figure S25 (see ESI)

**Figure 7** Electrostatic potential on the van-der-Waals surfaces of molecules **4a**, **4b**, **11a** and **11b** (top to bottom) in different orientations (left to right) for geometries optimized at the CAM-B3LYP 6-31+g(d,p) level of theory including solvent effects using the polarizable continuum model. Red, blue and black correspond to a positive, negative and vanishing electrostatic potential, respectively. Green and orange ellipses emphasize the two highly polar groups, namely the sulfonamide and the glycolic ester moieties, respectively.

shows that due to the hydroxy-ethyl groups attached to the sulfonamide in **5** and **12**, the sulfonamide gets even more polar and takes precedence, thus supposedly causing upright chromophore orientations.

#### Morphology and Optical Properties of Langmuir, LB and Spin Cast Films

To find out how the optical properties change with varying LB conditions, Langmuir-Blodgett-films (LB) were deposited on quartz-glass and characterized by means of UV/Vis-spectroscopy, fluorescence-measurements and atomic force microscopy (AFM). Spin-coated (SC) films and solutions were prepared as references. The two compounds **11a** and **11b** were investigated more closely because their LB isotherms differ significantly. Another advantageous feature of these two dyes is their comparatively high collapse-point, which allows varying  $\pi$  over a larger scale.

Employing AFM, we probed the surface morphology of LB- and SC-films of **11a** deposited onto a quartz glass surface to investigate the evenness of the films and the influence of the respective deposition method on film morphology. Height images as well as phase images, which probe the local stiffness of the film surface, are shown for **11a** in Figure 8. The LB and SC films have RMS surface roughnesses of 0.45 and 3.20 nm, respectively. Thus, the surface roughness of the SC film, expectedly, is significantly higher than that of the LB film. This can also be seen in the height images (see Figure 8a,c). A very narrow distribution of the AFM phase angle was observed for the LB film (Figure 8b) while the SC film shows significantly larger phase angles in areas where the surface is especially

**Figure 8** AFM images of LB- (a, b) and SC-films (c, d) of **11a**, deposited on quartz glass ( $\pi = 5$  mN/m). Individual scale bars are shown to the right of every image.

uneven (Figure 8d). Thus, smooth thin films with rather homogeneous molecular orientation are obtained via the LB-technique whereas spin-casting yields apparently stochastic molecular orientations and cluster formations and shows a significant amount of random substance accumulation.

The absorption spectra of **11a** and **11b** (chloroform solution, LB- and SC-film) are shown in Figure 9 (for the solid state samples the absorbance at the minimum was set to zero). The structureless band which appears at 390 nm in  $\text{CHCl}_3$  for **11a** and **11b** is red-shifted to 400 nm in the SC films. The LB films of 5 monolayers (ML) have been deposited at very high surface pressure (23 mN/m for **11a** and 28 mN/m for **11b**) and are expected to show a high molecular ordering. As seen from Figure 9 a higher molecular order in the LB-films as compared to the SC-films is revealed by the vibrational progression that is significantly better resolved in the spectra of the LB-films as compared to the SC-films (a simple estimation of the coupling energy in the vibrational progression gives an energy difference of about  $1350 \pm 100 \text{ cm}^{-1}$ ). Stochastic molecular orientations, like in the SC-films, are also present in Langmuir-films in the quasi liquid phase at low surface pressures. Thus, the transition from the disordered to the ordered phase can be mimicked by systematically varying the surface pressure at deposition of the Langmuir-films.<sup>61, 67</sup> The corresponding changes in the spectral shapes and vibrational progressions are shown in Figure 10. Interestingly the intensity distribution in the vibrational progression is altered from SC- to LB-films. Hence the potentials of the associated states are altered due to intermolecular interactions.

The dependence of the fluorescence spectra of **11a** and **11b** on the surface pressure was investigated directly for the Langmuir-films on the LB-trough surface by means of a custom-made fluorescence online-monitoring setup. Fluorescence spectra of **11a** that were normalized to the molecular density (same surface concentration) as obtained from the LB-isotherms are depicted in Figure 11. The fluorescence intensities increase with increasing surface

**Figure 9** UV/Vis-spectra of **11a** (left) in solution ( $\text{CHCl}_3$ ;  $c = 20 \mu\text{g/ml}$ ), as SC film ( $c = 2.16 \times 10^{-3} \text{ M}$ ; 30 rps for 30 s) and as LB film (5 ML;  $\pi = 20 \text{ mN/m}$ ). The intensity of the LB film was increased by factor 4 for clarity. UV/Vis-spectra of **11b** (right) in solution ( $\text{CHCl}_3$ ;  $c = 100 \mu\text{g/ml}$ ), as SC film ( $c = 2.14 \times 10^{-3} \text{ M}$ ; 30 rps for 30 s) and as LB film (5 ML;  $\pi = 32 \text{ mN/m}$ ).

**Figure 10** UV/Vis spectra of LB films at different  $\pi$  of **11a** (5 mL deposited at 4, 8, 12, 16, 20 and 23 mN/m, top) and **11b** (4, 8, 12, 16, 20 and 28 mN/m, bottom). The spectra have been normalized with regard to the molecule density per surface area.

pressure, which may be explained with a reduced misfit between the irradiation angle of excitation (intermediate incidence) and chromophore orientations. As can be seen from Figure 11, no distinct change in the spectral shape or wavelength of the fluorescence maximum occurs.

In contrast to **11a**, whose fluorescence intensity is increasing with increasing surface pressure, the fluorescence intensity of **11b** is almost constant when normalized with regard to the molecule density for low pressures ( $<1 \text{ mN/m}$ ) as shown in Figure 12. For these low surface pressures the fluorescence spectra become narrower for increasing surface pressures, but the maximum is retained at 460 nm, which is about the same value as found for THF-solutions of **11b** (see Table 2). When

further increasing the surface pressure, the shape of the fluorescence spectra changes: the band at 470 nm decreases while a second band at 542 nm almost retains its intensity, finally dominating the fluorescence spectrum at the rather large surface pressure of 27.55 mN/m.

The spectral changes of **11b** with increasing surface pressure can be explained in the following manner: At low surface pressures one can expect stochastically distributed dye molecules without appreciable intermolecular interaction, similar to solutions or amorphous phases. Indeed the optical properties of these LB-films are very similar to those of the dissolved samples. Further increase of the surface pressure is expected to cause alignment of the dyes and possibly

**Figure 11** Fluorescence of the Langmuir films of **11a** recorded at different  $\pi$ . The spectra were corrected by subtraction of a spectrum of the empty LB-trough and normalized with regard to the molecule density. Inset: Dependence of corrected fluorescence intensity on  $\pi$ .

formation of H-aggregates that are weakly fluorescent.<sup>68-70</sup> A further possibility for the steady reduction of the fluorescence at 470 nm might be an increasing misfit between the irradiation angle and chromophore orientations. However, the 542 nm-fluorescence that dominates the fluorescence spectrum at high surface pressures at deposition can be clearly assigned to an excimer emission as known from e.g. different perylene derivatives.<sup>71-73</sup> Other groups report similar findings for excimer emission bands in LB-films of pyrene,<sup>74</sup> indocarbocyanine<sup>75</sup> or merocyanine dyes.<sup>76</sup> Furthermore, the absence of a vibrational progression in the fluorescence spectrum supports the assignment to an excimer.

Figure 13 shows that the LB-films produced from **11a** exhibit the same spectral features as their Langmuir-analogues discussed above, except showing no systematic intensity trend, probably due to inhomogeneities that arose during the deposition. In case of **11b** all the essential features discussed for the Langmuir-films above are retained after deposition of corresponding LB-films as shown in Figure 13, particularly the intense excimer fluorescence at  $\pi = 28$  mN/m. To show the evolution of the excimer band with increasing surface

pressure, its intensity relative to the band at 470 nm (*i.e.*  $I(542 \text{ nm})/I(470 \text{ nm})$ ) is plotted versus the surface pressure in the inset in Figure 13.

## Experimental Section

**General Procedures and Molecular Characterization:** Reagents were purchased from commercial sources and were used directly unless otherwise stated. All solvents were of reagent grade and were dried according to common practice and distilled prior to use. Reactions were monitored by TLC, which was carried out on 0.2 mm Merck silica gel plates (60 F<sub>254</sub>). <sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded on Bruker Avance 250 and 400 spectrometers, chemical shifts ( $\delta$ ) are given relative to signals arising from the solvent. Mass spectra were recorded using a Finnigan MAT S50 710. Melting points were determined with a Cambridge Instruments Galen III apparatus (Boëtius system) and are uncorrected.

**Langmuir and LB-Films:** A KSV NIMA "alternate small" LB-trough with a Wilhelmy balance was employed for the  $\pi$ -A-isotherm measurements as well as the LB film preparations. A chloroform solution (for concentrations see Table 4) of the compound was placed at ambient temperature onto an aqueous subphase of ultrapure water (18 m $\Omega$  cm). The solution was spread on the surface with a pipette. In all cases films were compressed after 10 minutes allowing the chloroform to evaporate. The samples and the isotherms were fabricated with a constant compression rate of 375 mm<sup>2</sup>/min (barrier speed: 5 mm/min). The deposition of the layers on the quartz glass (30mm  $\times$  5mm  $\times$  1mm) was done using Y-type dipping (dipping speed: 5 mm/min) and keeping the monolayer under constant pressure. Prior to the transfer, the substrates were treated with chloroform, acetone and iso-propanol in the ultrasonic bath (each solvent 3 times for 10 min). The glass slides were stored under iso-propanol over night in order to make them hydrophilic.

**Atomic Force Microscopy:** AFM was carried out using a Veeco Digital Instruments Dimension 3100 AFM in tapping mode with a silicon tip (radius < 8 nm) at 300 kHz with a force constant of  $\approx 40 \text{ N m}^{-1}$  (Budget Sensors Tap 300-G).

**Figure 12** Fluorescence of the Langmuir films (**11b**) for several different  $\pi$ . The spectra were corrected by subtraction of a spectrum of the empty LB-trough and normalized to the molecule density per area.

**Figure 13** The fluorescence spectra of the LB films deposited at different pressures normalized to the molecule density (left: **11a**; right: **11b**). Inset: Ratio of the fluorescence intensities at 542 and 470 nm at different  $\pi$ .

**Spectroscopic Methods:** UV/Vis spectra (THF) were recorded with a PerkinElmer LAMBDA 45 UV/Vis spectrometer, emission spectra (THF) were recorded using a JASCO FP-6500 spectrofluorometer. Measurements of the fluorescence intensity were carried out on a PerkinElmer LAMBDA 45 UV/Vis spectrometer and JASCO FP-6500 spectrofluorometer in the perpendicular excitation–emission geometry, while the absorbance at the excitation wavelength used was adjusted to be between 0.04 and 0.05. The calculation of fluorescence quantum yields was done according to the following equation:<sup>77</sup>

$$\Phi = \Phi_r \frac{I}{I_r} \frac{A_r}{A} \frac{n^2}{n_r^2},$$

where  $\Phi$  is the quantum yield,  $I$  is the corrected integrated emission intensity,  $A$  is the absorbance at the excitation wavelength and  $n$  is the refractive index of the solvent. The subscript  $r$  refers to a reference fluorophore of known quantum yield. Here we used quinine sulfate ( $\Phi = 0.52$ )<sup>78</sup>. All thiazoles were excited as close as possible to their absorption maximum while staying inside the excitation range given in the literature.<sup>79</sup>

**Spectroscopic measurements of the compound films:** The fluorescence spectra were recorded on a home build setup. This consists of an Isoplan 320 Spectrograph with a cooled Pixis CCD-camera from Princeton Instruments. As excitation sources fiber coupled 5mW laser modules with different wavelength were used. Long pass filters with low self-fluorescence from ITOS were placed in front of the spectrograph to block scattered excitation light. The collected data were afterwards corrected by a self-written Labview program. This removes cosmic rays, filter self-fluorescence and accounts for the setup response function.

**Theoretical Methodology:** After an initial systematic conformational search with MMFF<sup>66</sup>, the best geometries were optimized using at the CAM-B3LYP/6-31+G(d,p)<sup>80, 81</sup> level of theory as implemented in Gaussian 09<sup>57</sup>. Ground state optimization and its validation via frequency calculation were followed by the calculation of the six lowest singlet excited states. This provided insight into the absorption properties of

the here presented compounds. Fluorescence emission was calculated according to Kasha<sup>82</sup> from the  $S_1$  equilibrium structure. The effects of solvation (THF) have been addressed state specific for all calculations of ground and excited states properties by means of the polarizable continuum model<sup>56</sup> as implemented in Gaussian 09.

**Synthesis of the compounds:** Detailed synthetic procedures can be found in the Supporting Information.

**Crystal Structure Determination:** The intensity data were collected on a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-K $\alpha$  radiation. Data were corrected for Lorentz and polarization effects; absorption was taken into account on a semi-empirical basis using multiple-scans.<sup>83–85</sup> The structure was solved by direct methods (SHELXS)<sup>86</sup> and refined by full-matrix least squares techniques against  $F_o^2$  (SHELXL-97)<sup>86</sup>. All hydrogen atoms were located by difference Fourier synthesis and refined isotropically. Mercury (Version 3.3 (Build RC5), Cambridge Crystallographic Data Centre) was used for structure representations.

## Conclusions

The present work describes the synthesis and photophysical properties of novel fluorescent and amphiphilic sulfonamide-substituted hydroxythiazole derivatives. Optical properties of these compounds have been investigated and quantum chemical calculations (CAM-B3LYP/6-31+G(d,p) level of theory) were performed in order to explain the experimental results. Structure-property relationships have emerged from a combination of experimental spectroscopic data and DFT/TDDFT calculations. Absorption and emission properties as well as quantum yields agree nicely with the quantum chemical calculations.

We further we showed how to exert direct control over the degree of aggregation in thin films made of different thiazole type dyes. Upon variation of the different substituents in 2- and 4-position and on the sulfonamide moiety (*i.e.* altering their relative polarity / anchoring strength) the chromophores can be oriented relative to the subphase surface of the LB-trough. In combination with spectroscopic investigations, we gained an in-depth understanding of the influence of aggregation on the electro optical properties of thin films made of the here investigated substances. In-depth investigations to gain detailed information on the molecular packing of our compounds in Langmuir and LB films are currently ongoing. A next step is to perform investigations on active layers or possibly entire devices. Work along these lines is currently in progress and will be reported in due course.
