π -Face-Selective 1,3-Dipolar Cycloadditions of 3,4-Di-*tert*-butylthiophene 1-Oxide with 1,3-Dipoles

Juzo Nakayama, Tomohiro Furuya, Yasuko Suzuki, Suguru Hiraiwa, and Yoshiaki Sugihara

Department of Chemistry, School of Science and Engineering, Saitama University, Saitama, Japan

3,4-Di-tert-butylthiophene 1-oxide underwent 1,3-dipolar cycloadditions with 1,3-dipoles such as nitrile oxide, diazomethane, nitrile imide, nitrone, and azomethine ylide at its syn- π -face with respect to the S=O bond.

Keywords 1,3-Dipolar cycloaddition; π -face selectivity; heterocycles; stereochemistry; thiophene 1-oxide

INTRODUCTION

 π -Facial selectivity (diastereofacial selectivity) in Diels–Alder reactions has been attracting considerable attention. It has been investigated most extensively by using 5-substituted cyclopentadienes as the diene.¹ Thiophene 1-oxides, which have the general structure shown in Figure 1, are no longer aromatic and hence highly reactive. They serve as a type of cyclic diene that possesses two π -faces, i.e., *syn-* and *anti*-faces, for Diels–Alder reactions, with respect to the S=O bond. We have reported that 3,4-di-*tert*-butylthiophene 1-oxide (1) undergoes *syn-* π -faceselective Diels–Alder reactions with a wide range of dienophiles.^{2–4} Recently, we also reported that the S₂O, formed by retro-Diels–Alder reaction of bicyclic compound **2**, disproportionates to S₃ (triatomic sulfur) and SO₂, and the resulting S₃ undergoes a *syn-* π -face-selective 1,3-dipolar cycloaddition to **1**, the counterpart of the S₂O formation, to give the final product **3**; the stereochemistry of **3** was determined by Xray diffraction analysis (Scheme 1).⁵ We have now examined 1,3-dipolar

cycloadditions of **1** with a series of 1,3-dipoles to know more about the stereochemical course of the reaction. To our knowledge, π -facial selectivity in 1,3-dipolar cycloadditions has been far less investigated.⁶⁻⁹

SCHEME 1 Syn- π -face-selective 1,3-dipolar cycloaddition of S₃ to thiophene 1-oxdide **1**.

Initially, 1,3-dipolar cycloadditions of 1 with propargyl-allenyl type 1,3-dipoles were examined. The reaction of 1 with acetonitrile oxide, generated in situ by reaction of nitroethane with phenyl isocyanate in the presence of Et₃N in CH₂Cl₂ at room temperature,¹⁰ furnished the single 1,3-dipolar cycloadduct $4a^{11}$ in 80% yield (Scheme 2). On the other hand, the reaction of 1 with benzonitrile oxide in CH₂Cl₂, generated by treatment of α -chlorobenzaldehyde oxime (PhCCl=NOH) with Et₃N,¹² afforded a 10:1 mixture of the two diastereomers 4b and 4b',¹¹ which were isolated in 80% and 7% yields, respectively. The ratio 4b:4b' showed solvent dependency; it was 23:1 and 24:1 in benzene and toluene, respectively.

The regiochemistry of the addition in the formation of 4a was determined by observation of the coupling (1.1 Hz) between H_a and the

SCHEME 2 1,3-Diploar cycloaddition of 1 with nitrile oxides.

oxazole methyl protons. The configuration of the sulfinyl group was determined on the basis of aromatic solvent-induced shift (ASIS) and $Eu(thd)_3$ -induced shift $[Eu(thd)_3;$ europium tris(2,2,6,6-tetramethyl-3,5-heptanedionate)]. It is well documented that benzene coordinates to the sulfur atom of the sulfinyl group,^{13–17} whereas the europium atom of $Eu(thd)_3$ coordinates to the oxygen atom. Thus, for the adduct 4a, the ¹H NMR spectrum in C₆D₆ would result in the high field shift of H_a and H_b, while the oxazole methyl signal remains virtually unchanged. On the other hand, $Eu(thd)_3$ would bring about the low field shift of H_a , H_b , and the methyl protons. Indeed, the spectrum in C_6D_6 resulted in the high field shift of H_a and H_b by 0.60 and 0.43 ppm, respectively, keeping the methyl signal virtually unchanged. Meanwhile, $Eu(thd)_3$ (0.2 molar amount) brought about the low field shift of H_a, H_b, and methyl signals by 0.52, 0.45, and 0.56 ppm, respectively. The ASIS and $Eu(thd)_3$ -induced shift for **4b** were similar to those described above. Meanwhile, H_a of **4b'** remote from the coordinated benzene showed a negligibly small ASIS (0.03 ppm low field shift), whereas $H_{\rm b}$ moved to a high field by 0.59 ppm. The above methods were also used for the determination of the stereochemistry of the other 1,3-dipolar cycloadducts described below.

The reaction of **1** with an equimolar amount of diazomethane at 0 °C produced the single adduct **4c**¹¹ in 93% yield (Scheme 3). In the ¹H NMR of **4c**, H_a appeared as a d/d (J = 9.5/8.0 Hz) due to the coupling with the methylene protons in agreement with the assigned regiochemistry. Incidentally, diphenyldiazomethane, trimethylsilyl azide, and phenyl azide failed to react with **1**.

SCHEME 3 1,3-Diploar cycloaddition of 1 with diazomethane.

Benzonitrile *N*-phenylimide (**6**), generated from **5**,¹⁸ added to **1** to furnish **4d**¹¹ in about 50% yield (Scheme 4).¹⁹ The structure of **4d** was determined by X-ray diffraction analysis (Figure 2).²⁰ Interestingly, methyl protons and methyl carbons of the*tert*-butyl group attached to the sp³ carbon appeared as a broad singlet both in the ¹H and ¹³C NMR spectra, probably because of the restricted rotation.

SCHEME 4 1,3-Diploar cycloaddition of 1 with nitirile imine 6.

Next, reactions with allyl type 1,3-dipoles were investigated. Heating equimolar amounts of 1 and nitrone 7 in refluxing toluene provided the sole adduct $4e^{11}$ in 61% yield (Scheme 5). Similarly, the reaction with nitrone 8 gave the adduct $4f^{11}$ in 73% yield.

The reaction of 1 with azomethine ylide 9,²¹ generated from three molar amounts of amine 10, gave a 10:1 diastereometric mixture of 4g and $4g'^{11}$ in good combined yield; only 4g was isolated in pure form in 73% yield (Scheme 6).

For the attempted reaction with carbonyl ylide **11**, its precursor tetracyanoethylene oxide **12** reduced **1** to give thiophene **13** and carbonyl cyanide**14**, as was reported by us.²² The reaction with ozone proceeded smoothly, but gave a complex mixture after treatment with Zn in acetic acid, from which a crystalline product, the structure of which could not be determined unambiguously, was isolated in low yield.

SCHEME 5 1,3-Diploar cycloaddition of 1 with nitrones 7 and 8.

SCHEME 6 1,3-Diploar cycloaddition of 1 with azomethine imide 9.

A Mulliken population analysis (B3LYP/6-31G* level²³) of 1 predicted that the positive charges are located at the 3- and 4-positions, while the negative charges are located at the 2- and 5-positions (Figure 3). Thus, the observed regioselectivity is in agreement with the electronic demand, where the positive end of 1,3-dipoles adds to the 2position, and the negative end adds to the 3-position. The observed regioselectivity is also in harmony with the steric demand that is brought about by bulky *tert*-butyl group. Only in the case of diazomethane, the steric demand governs the regiochemistry, where the less bulky negative end (diazo nitrogen) added to the congested 3-position, while the bulkier negative end (CH₂) added to the less congested 2-position.

As described above, the 1,3-dipolar cycloadditions of 1 took place preferentially at the syn- π -face to the S=O bond. This would best be explained as follows. The 1-oxide 1 has a bent structure at C₁ and C₄ with a tilt angle of 9.3° (Figure 4). Thus, for the syn- π -face addition, the transition state can be easily reached with a smaller conformational

FIGURE 2 ORTEP plot of molecular structure of **4d** in the crystal. Ellipsoids are drawn at 50% probability level.

FIGURE 3 Mulliken population analysis of 1 (B3LYP/6-31G* level).

FIGURE 4 Conformational changes required at the transition states.

change of **1**, whereas, for the *anti*-face addition, a larger conformational change is required to reach the transition state, where the inversion at C_1 and C_4 is required.²⁻⁴ Accordingly, the activation energy of the reaction would be smaller for the *syn*- π -face addition than for the *anti*- π -face addition, thus making the former process more favorable.
