Synthetic approaches to the furanocembrane family of natural products, *e.g.* lophotoxins, pukalides, bipinnatins, based on: i) an intramolecular cyclisation of an α,β-unsaturated acyl radical intermediate into a conjugated enone, *viz.* **18** → **17**, and ii) an intramolecular Stille coupling reaction involving a 2-stannylfuran and a vinyl iodide, *i.e.* **67** → **68**, are described. A total synthesis of bis-deoxylophotoxin **71a**, the probable biological precursor to the neurotoxin lophotoxin **1**, isolated from species of the Pacific sea whip *Lophogorgia*, is then presented.

Introduction

Lophotoxin **1**, together with pukalide **2** and bipinnatin G (**3**), and their various oxygenated and deoxygenated congeners are representative of a novel family of furanocembrane natural products isolated from marine soft corals and sea whips.[1] Lophotoxin is a particularly potent neurotoxin that binds selectively and irreversibly to acetylcholine recognition sites in nicotine acetylcholine receptors, leading to paralysis and asphyxiation.[2] Another family of interesting furanoterpenoid natural products are the pseudopteranes, represented by kalloide A (**4**)[3] and pseudopterolide **5**,[4] which have 12-membered rings, instead of the 14-membered rings found in cembrane diterpenes. The range and variation in structure of furanoditerpenes found in soft corals increases annually, including the recent isolation of the dimer mayotolide A (**6**)[5] and the first α-ylidenecyclobutanol member providencin **7**.[6] With the plethora of interesting structural variations found within the furan-based diterpenes, alongside the novel biological properties found within their members, it is not surprising that synthetic chemists have been lured into studies of the total synthesis of these deceptively straightforward structures.[7] Paquette and co-workers[8] were the first to complete a synthesis of a furanocembrane, *i.e.* acerosolide **8**, and also a pseudopterane, *i.e.* gorgiacerone **9**, using a macrocyclisation strategy based on a Nozaki–Hiyama–Kishi protocol. More recently, Marshall *et al.*[9] have described total syntheses of kalloide A (**4**), rubifolide **10** and *Z*-deoxypukalide **11**, using an efficient intra-annular furan ring formation *via* either a conjugated allenone or an α-keto acetylene intermediate[10] in the latter two cases. In some earlier studies, published in 1991, we described an approach to the furanocembrane core in the lophotoxins, pukalides, and bipinnatins based on an intramolecular 14-*endo*-trig acyl radical cyclisation from the α,β-unsaturated phenyl seleno ester **12** in the presence of Bu_3SnH–AIBN leading to the macrocyclic 1,4-dione **13** in 40% yield.[11] Subsequent treatment of **13** with *p*-TSA in hot chloroform then resulted in furan ring formation, leading to the furanocembrane **14**. In later investigations we developed an alternative approach to the furanobutenolide cembrane core **16** in the same families of natural products using an intramolecular Stille reaction from the iodo-stannane **15** as the key stratagem.[12] In this paper we describe the outcome of our attempts to extend

the radical macrocyclisation strategy, *viz.* **12** → **13**, to more oxygen-functionalised acyl radical precursors, and full details of a synthesis of deoxylophotoxin using the aforementioned intramolecular Stille reaction as the key reaction.

Results and discussion

The α,β-unsaturated acyl radical macrocyclisation approach

Over several years we have developed and tested the scope of a number of alkyl radical macrocyclisation reactions in the synthesis of natural products,[13] including the cembrane mukulol[14] and the oestrogenic mycotoxin zearalenone.[15] We have also used radical macrocyclisation reactions in tandem with radical transannulation reactions to synthesise a range of polycyclic constructs, especially steroids.[16] At the outset of our investigations into the scope of α,β-unsaturated acyl radical intermediates in the synthesis of furanocembranes, very little was known about the reactivity profile of these unusual species. Indeed, to our knowledge, the cyclisation **12** → **13** we had developed in 1991, *en route* to the furanocembrane core **14** in lophotoxin, was unprecedented.[11] The success of this model reaction gave us the confidence to develop a strategy to the more elaborate oxygen-substituted seleno ester **18**, and then to study its conversion into bis-deoxylophotoxin **17b**, as a precursor to lophotoxin **1** itself. Accordingly, we decided to prepare the selenoester **18** *via* an intermolecular alkylation reaction between the enantiopure phenylselenolactone **19** and the chiral γ-unsaturated aldehyde **20** (Scheme 1).

Thus, a regioselective ring opening of the epoxide **22** derived from (+)-glutamic acid[17] with the high-order cuprate prepared from the vinyl bromide **21**[18] first gave the α-hydroxy ester **23** in 70% yield (Scheme 2). Treatment of **23** with LDA in THF at −78 °C next gave the corresponding γ-lactone (**24**; 91%) which was then re-treated with LDA and quenched with phenylselenium bromide leading to the phenylselenolactone **19** as a 2 : 1 mixture of diastereoisomers.

The γδ-unsaturated aldehyde **20** was prepared in six straightforward steps starting from 5,6-dihydro-2*H*-pyran-2-one **25** (Scheme 3). Treatment of **25** with the high-order cuprate derived from 2-bromopropene first led to the racemic δ-lactone **26** which could be resolved *via* its 2-methylphenylamide derivative **27**[19] to provide the required *S*-enantiomer **28**. Reduction of the δ-lactone **28**, using DIBAL, next gave the corresponding lactol **29** which underwent smooth alkylation with the dianion produced from 2-bromopropen-1-ol[20] leading to the triol **30** as a 2 : 1 mixture of diastereoisomers. After protection of **30** as the corresponding benzylidene acetal **31**, oxidation under Swern conditions finally gave the γδ-unsaturated aldehyde **20**.

Treatment of the phenylselenolactone **19** with LDA at −78 °C followed by alkylation of the resulting carbanion with the aldehyde **20** led to the adduct **32** which was immediately subjected to oxidative dehydroselenylation, using H_2O_2 in aq. THF, resulting in the formation of a mixture of diastereoisomers of the unsaturated lactone **33a** (Scheme 4). The secondary hydroxyl group in **33a** was next protected as its acetate **33b** and then the silyl ether group was deprotected revealing the primary alcohol **34a**. Oxidation of **34a**, using Dess–Martin periodinane, followed by oxidation of the resulting α,β-unsaturated aldehyde **34b**, next gave the corresponding carboxylic acid **34c**.[21] Treatment of the acid **34c** with *N*-phenylselenophthalimide and Bu_3P[22] then produced the phenylselenoester **35** which, to our surprise, was found to be a 1 : 1 mixture of *Z*- and *E*-isomers. In pursuit of the key intermediate **18**, the benzylideneacetal group in **35** was removed using PPTS-MeOH, and the resulting doubly allylic alcohol **36** was converted, into the PMB ether **37**[23] and then into the conjugated enone **18** using standard reagents and conditions (Scheme 4).

Much to our chagrin, when the phenylselenoester **18** was treated under identical radical-initiating conditions to those used to convert **12** into **13** (*en route* to **14**) we were not able to detect the macrocylclic 1,4-dione corresponding to **13** amongst the mixture of products. Although the availability of material and spectroscopic data did not allow any unambiguous assignment, the dearth of olefinic proton signals in the NMR spectra in the products suggested that the unsaturated acyl radical **38** produced from the phenylselenoester **18** had most likely undergone a sequence of alternative radical cyclisation reactions leading to a polycyclic structure similar to the spirotetracycle **43**. The production of this unusual structure could be rationalised through isomerisation of the initially produced *E*-α,β-unsaturated acyl radical **38** into the corresponding *Z*-isomer **40** *via* the novel α-ketene alkyl radical species **39** followed by: (i) 6-*exo*-trig acyl radical cyclisation into the adjacent butenolide double bond, leading to **41**, (ii) 6-*endo*-trig cyclisation of **41** to **42**, and finally, (iii) 6-*endo*-trig cyclisation of the radical **42** into the proximate enone electrophore producing the tetracycle **43** (Scheme 5). Although this analysis is speculative and the structure of **43** is complete conjecture, precedent for the isomerisation of *E*- and *Z*-α,β-unsaturated acyl radicals *via* ketene alkyl radical species, *viz.* **39**, can be found in our contemporaneous studies directed towards a synthesis of the PAF antagonist phomactin

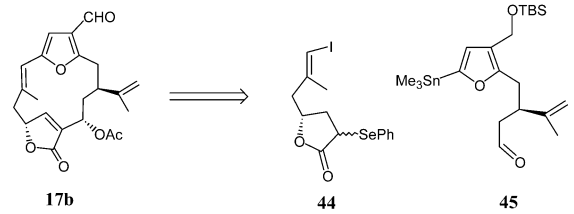
A.[24] Indeed, the scope for ketene alkyl radical species in synthesis has been subsequently developed by us and provided, *inter alia*, new syntheses of triquinanes *e.g.* pentalenene[25] and modhephene.[26] Notwithstanding these subsequent studies, it was clear that the proposed route to furanoterpenes *via* intramolecular cyclisation of α,β-unsaturated acyl radical intermediates into enone electrophores had limitations, and it was abandoned in favour of a Stille coupling approach, which is described below.

The Stille coupling reaction approach

The Stille sp^2–sp^2 coupling reaction between alkene partners is one of the most revered contemporary synthetic methods.[27] The method has been applied widely in the synthesis of a range of target natural products including some from our own laboratory *e.g.* recently pateamine A, rhizoxin D, amphidinolide A.[28] Working alongside these contemporaneous investigations we designed a new approach to a synthesis of the bis-deoxylophotoxin **17b** based on sequential carbanion alkylation and Stille coupling between the enantiopure selenolactone-substituted vinyl iodide **44** and the enantiopure stannylfuran-substituted aldehyde **45**.[12]



The selenolactone **44** was synthesised from the (*R*)-epichlorohydrin[29] *via* the known (*R*)-chlorotrimethylsilylpent-4-yn-2-ol **46a**[30] in six straightforward steps as shown in Scheme 6. Thus, the silane **46a** was first deprotected to the monosubstituted acetylene **46b**. Carbometalation–iodination[31] of **46b** next gave the *E*-vinyl iodide **47**, which was smoothly converted into the corresponding epoxide **48** in the presence of NaOH. Treatment of **48** with the lithium salt of 1-ethoxyacetylene, followed by reaction with *p*-TSA, work up and chromatography next gave the enantiopure lactone **49** as an oil.[32] When the lactone **49** was deprotonated with LiHMDS and the resulting anion was quenched with phenylselenium bromide at −78 °C,[33] a 2 : 1 mixture of diastereoisomers of the α-phenylselenolactone **44** was obtained, but only in modest yield. A by-product from

the reaction was the corresponding bis-selenated lactone **50**. The formation of this bis-selenated lactone **50** could be avoided completely, however, by trapping the intermediate lithium enolate **51** derived from **49** with trimethylsilyl chloride.[34] Subsequent treatment of the TMS ether **52** with phenylselenium bromide then gave the α-phenylselenolactone **44** as the sole product in 72% yield (Scheme 6).

The stannylfuran-substituted aldehyde **45** was prepared starting with the oxazolidinone **54** derived from 3-methylbutan-2-oyl chloride and the chiral oxazolidinone **53**.[35] Deprotonation of the imide **54** with NaHMDS in THF at −78 °C, followed by addition of ethyl 2-bromomethyl-3-furoate[36] first gave the adduct **55a** resulting from deconjugative alkylation (Scheme 7). The relative stereochemistry of **55a** was established from X-ray measurements on the corresponding crystalline methyl ester **55b**, mp 59–61 °C.[37] Reduction of **55a**, using two equivalents of Super Hydride produced the alcohol **56**, which was then converted into the corresponding nitrile **57a** in three straightforward steps. After protection of the alcohol **57a** as its TBS ether **57b**, the nitrile group was reduced to the aldehyde **58**, which, on further reduction with $NaBH_4$, gave the alcohol **59**. Initial attempts to deprotonate the furan ring in **59** at the C-5 position were not successful.[38] We eventually achieved this objective, however, by treating **59** with an *excess* of *n*-BuLi in the presence of TMEDA at room temperature.[39] When the resulting furyllithium species was then quenched with Me_3SnCl, the desired stannylfuran **60** was isolated in 83% yield. Oxidation of the alcohol group in **60** using TPAP[40] finally gave the stannylfuran-substituted aldehyde **45**.

The proposed union of the stannylfuran **45** with the vinyl iodide **44** was first examined using an intermolecular Stille reaction between **60** and **44** in the presence of Pd_2dba_3–Ph_3As[41] which, gratifyingly, led to the coupled product **61a** in 55% yield (Scheme 8). With the aim of carrying out an intramolecular alkylation reaction, the alcohol **61a** was converted into the corresponding mesylate **61b**, but all attempts to induce macrocyclisation from this substrate under a variety of different conditions (solvent, base, temperature) met with failure. Similarly, we were also not able to effect macrocyclisation from the analogous lactone iodide **62** (prepared from **49** and **60**) under a variety of reaction conditions.

We then decided to combine **44** with **45** by carrying out the alkylation step first, followed by the Stille coupling reaction in an intramolecular fashion, as the final step.[42] This proposition was first modelled using the stannylfuran **45** and the lactone vinyl iodide **49** which was devoid of selenium substitution. Thus, alkylation of the anion derived from **49** using LiHMDS in THF

at −78 °C, with the aldehyde **45** gave the unstable secondary alcohol adduct **63** as an oil in 71% yield. An intramolecular Stille coupling reaction with **63**, under high dilution, then gave the furanocembrane **64** as a separable mixture of α- and β-OH epimers, in 41% yield (Scheme 9). The important feature of retention of the *E*-geometry of the trisubstituted double

bond in the vinyl iodide **63** during the Stille coupling was confirmed by carrying out detailed NOE experiments with the furanocembrane **64**.[43] Furthermore, acetylation of the major epimeric alcohol resulting from the macrocyclisation, followed by deprotection of the resulting TBS ether **65a** led to a single isomer of the furanylmethanol **65b**. Oxidation of the alcohol **65b** led to the corresponding aldehyde **65c**, which was obtained as a colourless crystalline solid. X-Ray crystallographic analysis of this cembrane then established its relative stereochemistry, which is shown in Fig. 1.[37]

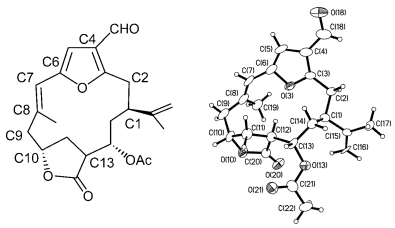

Fig. 1 X-Ray crystal structure of the furanocembrane **65c**.

With the aforementioned model studies, we next examined the same sequence of carbanion alkylation and Stille coupling reactions starting with the phenylselenyl-substituted lactone **44**. Deprotonation of the lactone **44**, using LiHMDS in THF at −78 °C, followed by addition of the aldehyde **45** gave the corresponding alkylated product **66** as a mixture of diastereoisomers in 93% yield (Scheme 10). After some optimisation of reaction conditions, to avoid significant destannylation of the sensitive stannylfuran unit in **66**/**67**, oxidative elimination of the phenylselenide residue in **66** using H_2O_2 in CH_2Cl_2–pyridine gave the butenolide **67**. An intramolecular Stille reaction with **67** under the conditions described by Farina *et al.*[41] then led to the

furanocembrane **68**, which was obtained as a mixture of epimeric alcohols. Without purification, the labile furanocembrane **68** was acetylated *in situ* to give the corresponding acetate **69** as a 2.3 : 1 mixture of OAc epimers in 20% yield over two steps. Deprotection of the TBS group in **69** then gave the 3-furanylmethanol **70**, from which the major (presumed α-OAc) epimeric acetate could be separated by chromatography. Finally, oxidation of the α-acetate **70**, using Dess–Martin periodinane, gave bis-deoxylophotoxin **71a**. Corresponding oxidation of a 2 : 1 mixture of OAc epimers of **70** led to a mixture of OAc epimers of **71**. The structures of the α- and β-OAc epimers of bis-deoxylophotoxin followed from comparison of their NMR spectroscopic data with each other and with those of naturally occurring furanocembranes.

The family of furanocembranes represented by lophotoxin **1**, pukalide **2** and bipinnatin G (**3**) are deceptively demanding targets for total synthesis. In this paper we have highlighted the scope for two quite different synthetic approaches to these targets which complement the contemporaneous synthetic work of others and notably the studies of Paquette and Marshall and their respective co-workers. Clearly there remains scope for further innovation in this area, and particularly when it comes to addressing the issue of introducing the epoxide functionalities in furanocembranes such as **1**–**3** in both a chemo- and stereoselective manner.

General details

^{1}H NMR spectra were recorded on either a Varian 270 (270.13 MHz), a Bruker DPX 360 (360.13 MHz), a Bruker AV 400 (400.13 MHz), or a Bruker DRX 500 (500.12 MHz) spectrometer. Proton chemical shifts are quoted in parts per million (ppm), and spectra were referenced to residual protonated solvent (δ_H = 7.27 for $CDCl_3$). Abbreviations used in the description of resonances are: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), bs (broad singlet) and bd (broad). Coupling constants (J) are quoted to the nearest 0.1 Hz. ^{13}C NMR spectra were recorded either on a Varian 270 (67.8 MHz), a Bruker DPX 360 (90.03 MHz) or a Bruker DRX 500 (125 MHz) spectrometer with complete proton decoupling. Carbon chemical shifts are quoted in parts per million (ppm) and spectra were referenced to residual protonated solvent (δ_C = 77.1 for $CDCl_3$). Assignments were made on the basis of chemical shift using the DEPT sequence with secondary pulses at 90° and 135°, where appropriate. In the spectroscopic data, C refers to quaternary carbon, CH to tertiary methine, CH_2 to secondary methylene and CH_3 to primary methyl.

Infra-red spectra were recorded using a Perkin–Elmer FT 1600 spectrometer as dilute solutions in spectroscopic grade chloroform or deuterated chloroform.

Mass spectra were recorded either on a VG Autospec, MM-701CF, or a Micromass LCT spectrometer using electro ionisation (EI), fast atom bombardment (FAB), or electrospray (ES) techniques. High-resolution mass spectra are calculated from the molecular formula corresponding to the observed signal using the most abundant isotopes of each element, to 4 decimal places.

Optical rotations were recorded on a JASCO DIP 370 polarimeter and melting points were recorded on a Stuart Scientific SMP3 melting point apparatus, and are uncorrected. Flash chromatography was carried out on Merck silica gel 60 (230–400 mesh ASTM) as the stationary phase or alumina Woelm basic (cationotropic), where indicated. Petroleum ether refers to the fraction b.p. 40–60 °C unless stated otherwise. All chemical reactions were monitored by thin layer chromatography (TLC) using Merck silica gel 60 F_{254} precoated aluminium plates or Merck aluminium oxide F_{254} plates, which were visualised under

ultraviolet light and then developed with either basic potassium permanganate solution or acidic alcoholic vanillin solution.

Unless stated otherwise, reactions requiring anhydrous conditions were conducted under an inert atmosphere of nitrogen in flame-dried or oven-dried apparatus. When necessary, solvents were dried prior to use. Dichloromethane was either distilled from calcium hydride or was obtained in high-grade form from Fisher-Scientific. MeOH was distilled from magnesium methoxide, and ether and tetrahydrofuran from sodium metal and benzophenone ketyl. Anhydrous *N*,*N*-dimethylformamide (DMF) and 1-methyl-2-pyrrolidinone (NMP) were purchased from Aldrich.

(3*S*)-3-Isopropenyl-5,7-*O*-benzylidene-6-(methylene)heptanal 20. Dimethyl sulfoxide (0.21 mL, 2.84 mmol) was added dropwise over 5 min to a stirred solution of oxalyl chloride (0.13 mL, 1.42 mmol) in dry CH_2Cl_2 (6 mL) at 0 °C. The mixture was stirred at this temperature for a further 5 min before it was cooled to −78 °C and a solution of the alcohol **31** (0.21 g, 0.71 mmol) in dry CH_2Cl_2 (2 mL) was then added dropwise over 1 min. The mixture was stirred at −78 °C for 2 h and then quenched by the addition of triethylamine (0.96 mL, 9.28 mmol) at −78 °C and subsequently warmed to room temperature. The mixture was diluted with CH_2Cl_2 (30 mL) and washed with water (50 mL). The aqueous layer was further extracted with CH_2Cl_2 (2 × 30 mL) and the combined organic extracts were then washed with brine (30 mL), dried ($MgSO_4$), and evaporated *in vacuo* to leave a yellow-brown oil. A solution of sodium chlorite (0.09 g, 0.98 mmol) and potassium dihydrogen ortho phosphate (0.1 g, 0.77 mmol)[21] in water (3.2 mL) was added to a stirred solution of the aldehyde **34b** (54 mg, 0.11 mmol) in *tert*-butanol (6 mL) and 2-methyl-2-butene (3 cm^3) at room temperature. The mixture was stirred for 7 h and then evaporated *in vacuo*. The aqueous residue was extracted with diethyl ether (3 × 10 mL) and the combined organic extracts were dried ($MgSO_4$), and evaporated *in vacuo* to leave the carboxylic acid **34c** (quantitative conversion) as a colourless oil.

Tri-*n*-butylphosphine (0.03 mL, 0.12 mmol) was added dropwise over 5 min to a stirred solution of the carboxylic acid (11.2 mg, 0.02 mmol) in dry CH_2Cl_2 (1.5 mL) at −30 °C. *N*-Phenylselenophthalimide (36 mg, 0.12 mmol) was added in one portion and the mixture was stirred at −30 °C for 2 min.[22] The cold bath was removed and the reaction immediately warmed to room temperature. The solution was stirred at room temperature for 25 min and then diluted with CH_2Cl_2 (5 mL) and extracted with 5% potassium carbonate solution (5 mL). The aqueous layer was further extracted with CH_2Cl_2 (2 × 5 mL) and the combined organic extracts were dried ($MgSO_4$), and evaporated *in vacuo* to leave a yellow oil. Much later, we investigated this intramolecular radical cyclisation in more detail to ascertain whether or not the *E*-geometry of the alkene bond in the α,β-unsaturated selenoester **12** underwent any *E*-to-*Z* equilibration during acyl radical formation. Interestingly, in addition to isolating the *E*-macrocyclic dione **13a** (38%) we also separated smaller amounts (~17%) of the corresponding *Z*-isomer **13b**. The *Z*-stereochemistry of **13b** followed from NOE experiments. M. Cases, unpublished observations.
