### Prins Cyclizations in Au-Catalyzed Reactions of Enynes\*\*

Eloísa Jiménez-Núñez, Christelle K. Claverie, Cristina Nieto-Oberhuber, and Antonio M. Echavarren\*

The hydroxy- or alkoxycyclization of enynes **I** catalyzed by electrophilic transition-metal complexes usually takes place through cyclopropyl metal carbenes **II**, which react with nucleophiles R'OH to give intermediates **III** (Scheme 1). The reaction is then terminated by proto-demetalation of the alkenyl metal intermediate **III** to give  $\mathbf{IV}$ .<sup>[1,2]</sup>

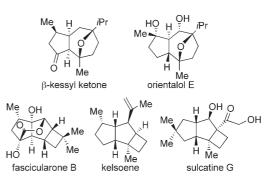

**Scheme 1.** Different evolution of intermediate **III** by proto-demetalation of the Prins reaction with oxonium cations via **V** or **VI**.

We have now found that in the Au<sup>1</sup>-catalyzed cyclization of enynes<sup>[3,4]</sup> the alkenyl metal intermediate can be trapped with appropriate substituents, as shown in **V** and **VI** in a Prins cyclization. These new cyclizations allow the one-step synthesis of tricyclic skeletons, such as those of  $\beta$ -kessyl ketone<sup>[5a]</sup> and orientalol E (Scheme 2),<sup>[5b]</sup> from enynes with carbonyl groups and octahydrocyclobuta[*a*]pentalenes, such as fascicularone B,<sup>[6]</sup> kelsoene,<sup>[7]</sup> and sulcatine G,<sup>[8]</sup> starting from cyclopropyl enynes.

Enynes **1a**–c, bearing a carbonyl group at the alkenyl side chain, are cyclized to give oxatricyclic derivatives **2a**–c and rearranged ketones **3a–c** by using Au<sup>I</sup> catalysts (Table 1). The

<sup>[</sup>a] Reactions at 23 °C with 3 mol% catalyst for 5–30 min (100% conversion). **A**: [Au(PPh<sub>3</sub>)Cl]/AgSbF<sub>6</sub>, **B**: [Au(PPh<sub>3</sub>)(MeCN)]SbF<sub>6</sub>, t-Bu, t

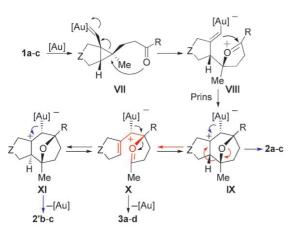

reactions were completed at room temperature in 5–30 min. Aldehyde **1a** gave a mixture of tricycle **2a** (35%) and ketone **3a** (50%) with [AuCl(PPh<sub>3</sub>)]/AgSbF<sub>6</sub> (catalyst **A**; Table 1, entry 1). Similar results were obtained with [Au(PPh<sub>3</sub>)-(MeCN)]SbF<sub>6</sub> (catalyst **B**) and cationic complex  $C^{[3]}$ (Table 1, entries 2 and 3). A yield of 58% for **2a** was achieved by using AuCl itself (Table 1, entry 4). In the cyclization of ketones **1b** and **1c**, **2'b**,**c** were obtained as minor isomers, although their formation could be minimized by using Au<sup>I</sup> catalysts **B** or **C** (Table 1, entries 6/7 and 10/11). Results with catalysts **A** and **B** were not identical (compare entries 5/6 and 9/10), which suggest that Ag<sup>I</sup> may not be innocent in some of these cyclizations.<sup>[9]</sup> The best yields of **2b–c** were achieved with AuCl (Table 1, entries 8 and 12). Substrate **1d** led only to ketone **3d** (77%; Table 1, entry 13).

The structures of **2a–d** were assigned by NMR spectroscopic analysis and by the X-ray diffraction determination of **2c**.<sup>[10]</sup> The *cis* configuration of ketones **3a–d** was based on the coupling constant  ${}^{3}J = 11.6$  Hz, as observed for **3a** and in NOESY experiments.

The carbonyl group acts as an internal nucleophile in the cyclizations of Table 1, as shown in **VII** (Scheme 3), thus

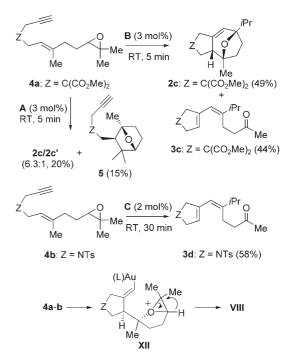

Scheme 3. Proposed mechanism for the cyclization of enynes 1 a-c.

forming oxonium cation **VIII**, which undergoes a Prins reaction<sup>[11]</sup> to give **IX**. Intermediate **IX** is a substituted 4tetrahydropyranyl cation, which has been shown to be aromatic.<sup>[12]</sup> Elimination of the metal fragment forms tricycles **2a–c**. Alternatively, an elimination with fragmentation of the seven-membered ring via **X** leads to carbonyl compounds **3a– d**. Minor epimers **2'b, c** can arise by a competitive 2-oxonia– Cope rearrangement<sup>[13]</sup> via **X** and **XI**.

The higher selectivity for the formation of tricycles **2a–c** using AuCl as the catalyst (Table 1, entries 4, 8, and 12), relative to the cationic complexes **A–C** could be explained by the faster elimination of the more electron-rich metal center in **IX**, whereas for complexes **A–C** the metal center does not bear a negative charge in intermediates **VIII–XI**.

Interestingly, **2c** was also obtained from epoxide **4a** by using catalyst **B** (Scheme 4).<sup>[14]</sup> On the other hand, the reaction of **4a** with catalyst **A** gave a mixture of **2c/2'c** and oxonorbornane **5**, whose structure was confirmed by X-ray crystallography.<sup>[10]</sup> Epoxide **4b** reacted with catalyst **C** to give ketone **3d**, a result similar to that from **1d** (Table 1, entry 13). The formation of **2c** and **3c**, **d** could proceed through intermediates **XII**, which suffer C–O bond cleavage followed by a 1,2-hydrogen shift to form **VIII** ( $\mathbf{R} = i\mathbf{Pr}$ ). Model epoxides do not isomerize to the corresponding carbonyl compounds under these reaction conditions.<sup>[15]</sup> We did not observed the direct addition of the ketone or the epoxide to the alkyne in any of these cyclizations.<sup>[16]</sup>

A related Prins cyclization, which leads to tricycles with an octahydrocyclobuta[*a*]pentalene skeleton (see Scheme 2), was uncovered in the cyclization of cyclopropylenynes **6a**–  $d^{[17-19]}$  (Table 2). Thus, the reaction of ethyl ether **6a** with Au<sup>1</sup> gave tricycles **7a**/**7'a** (Table 2, entries 1–3). Interestingly, *syn*-**7'a** was favored with catalyst **C** in the presence of traces of

water, whereas the use of AuCl led to the formation of **7a**, although the reaction was relatively slow (Table 2, entries 2 and 4). Low conversions (ca. 20%) were obtained when this reaction was carried out in the presence of 4-Å molecular sieves. Cycloprolylenynes **6b–d** reacted to give tricycles **7b–d** (Table 2, entries 5–9). Cyclobutanones were also formed as minor side products in these reactions.<sup>[20,21]</sup>

A rationale for the results of Table 2 is provided in Scheme 5. Accordingly, **XIII** forms cyclopropyl metal carbene

*Scheme 5.* Proposed mechanism for the gold-catalyzed reaction of enynes **6a–d**.

**XIV**, which undergoes ring expansion to form **XV**. The alkenyl gold complex of **XV** could react with the oxonium cation to form **XVI**, which upon demetalation forms tricycles **7a–d** by a Prins reaction.<sup>[11]</sup> The concerted pathway (**XIV** $\rightarrow$ **XV**) is favored with AuCl as the catalyst, whereas cationic Au<sup>I</sup> complexes apparently favor a nonconcerted reaction via cyclopropyl-stabilized cation **XVII**,<sup>[22]</sup> which undergoes a non-stereospecific ring expansion to give mixtures of **7a–d**. **7'a–d**.<sup>[23]</sup> However, as suggested by the dependence of the stereochemical outcome on the amount of water, we cannot exclude a pathway in which water opens intermediate **XIV** to form an alcohol, followed by a pinacol-type expansion. This process would result in an overall retention of configuration to form **XV**'.

Tricycles 7e/7'e were directly obtained when the synthesis of **6k** was attempted by the cyclopropanation of dienyne **8** with the Furukawa reagent<sup>[24]</sup> (-65 $\rightarrow$ 23 °C; Scheme 6). This result is consistent with the mechanistic hypothesis of Scheme 5, in which the nonconcerted pathway is favored with Zn<sup>II</sup> through intermediates **XV**', thus leading to *syn,cis* diastereomer **7'e** as the major tricycle.

**Scheme 6.** Direct Zn<sup>II</sup>-promoted cyclopropanation/cyclization of enyne **8**.

In summary, the alkenyl gold intermediate formed in the cyclization of enynes can be trapped in 5-*exo-dig* or 6-*endo-dig* Prins reactions to form an additional C–C bond. These Au<sup>1</sup>-catalyzed cyclizations of functionalized enynes led to the ready assemblage of tricyclic carbon skeletons that are present in a number of naturally occurring compounds. Thus, for example, tricycle **2c**, which possesses the same skeleton and relative configuration of  $\beta$ -kessyl ketone and orientalol E (Scheme 2), can be obtained in high yield in a

single step. The transformation of 1a-d into ketones 3a-d represents a new type of skeletal rearrangement of enynes.
