Temperature-programmed NO₂ emissions from frozen aqueous NaNO₃ solutions irradiated at 313 nm were monitored as function of nitrate concentration and heating rate, *H*, above −30 °C. Emissions increase nonmonotonically with temperature, displaying transitions suggestive of underlying metamorphic transformations. Thus, NO₂ emissions surge at ca. −8 °C in frozen [NO₃[−]] > 200 μM samples warmed at *H* = 0.70 °C min^{−1} under continuous irradiation, and also in the dark from samples that had been photolyzed at −30 °C. The amounts of NO₂ released in individual thermograms, Σ_N, increase less than linearly with [NO₃[−]] or the duration of experiments, revealing the significant loss of photogenerated NO₂. The actual Σ_N ∝ [NO₃[−]]^{1/2} dependence (at constant *H*) is consistent with NO₂ hydrolysis: 2NO₂ + H₂O → NO₃[−] + NO₂[−] + 2H⁺, overtaking NO₂ desorption, even below the eutectic point (−18 °C for aqueous NaNO₃). The increasingly larger NO₂ losses detected in longer experiments (at constant [NO₃[−]]) are ascribed to secondary photolysis of trapped NO₂. The relevance of present results to the interpretation of polar NO₂ measurements is briefly analyzed.

Introduction

The even distribution of nitrate across Greenland and Antarctica arises from remote sources convolved with long distance atmospheric transport.^{1–4} Nitrate depth profiles in polar ice should provide, therefore, a valuable record of global paleoatmospheres, were they preserved over geological times. However, nitrate (molar absorptivity: ε_{310 nm} = 7.5 M^{−1} cm^{−1})^{5,6} undergoes solar photolysis in the snowpack, thereby releasing NO_x into the overlying atmosphere,^{7–16} and compromising its documental value.^{6,17} The •OH radicals generated in reaction 1 and 3,^{18–23} can also drive the oxidation of organic matter within snowpacks.^{24–26}

The reaction medium in which these processes take place is deemed to remain fluid well below 0 °C because: (1) NO₂[−] and NO₂ formation rates in ice and water do not exhibit discontinuities about the freezing point,^{27–29} and (2) NO₂[−] production rates are significantly enhanced by formate, as a nongeminate •OH scavenger, in both fluid and frozen solutions.²⁸ NO_x emission rates from irradiated frozen nitrate solutions are partially controlled by reaction 1:²⁷ photogenerated NO₂ is significantly delayed in subsurface layers prior to desorption.²⁷ We now report temperature-programmed NO₂ photodesorption

rates from nitrate-doped polycrystalline ice as a function of nitrate concentration and heating rates that provide direct information on the mechanism and extent of nongeminate NO₂ reconversion into nitrate, and on the photolysis of trapped NO₂.

Experimental Methods

A schematic representation of the LIF detection setup, which is directly coupled to the photoreactor,³⁰ is shown in Figure 1. About 4–5 mL of pre-cooled aqueous NaNO₃ (EM Science) solutions (2 μM to 50 mM) was sprayed onto a coldfinger (CF in Figure 2, *A* = 304 cm²) to produce nitrate-doped polycrystalline ice (NDI) layers with an average thickness of δ ~150 μm. The ice temperature was controlled with an external cryogenic unit (Thermo Neslab ULT-80), which circulated refrigerated fluid through the interior of the CF. The ice-covered CF was encased within a sealed quartz sheath (QS), placed in a reflective cylindrical stainless steel chamber, and illuminated by four Hg Pen-Ray UV lamps (UVP, model 90-0001-04) emitting at λ = 313 ± 20 nm. The photon irradiance incident on the QS, *I*_i = 3.0 × 10¹⁵ photons cm² s^{−1}, was determined using potassium ferrioxalate as a chemical actinometer.³¹ The lamp stability was monitored by a photocell located on the top of the reflective chamber. The NDI matrixes, initially held at ca. −30 °C, were heated at *H* = 0.70, 0.30, or 0.10 °C min^{−1} up to 5 °C during or, in some specific experiments described below, after irradiation. The photogenerated NO₂ was continuously flushed with zero-air carrier gas, *F*_C = 2.5 L min^{−1} at 1 atm, into the detection zone.³⁰ Laser induced NO₂ fluorescence signals were detected with a sensitivity of 5 pptv/min.³⁰

Results and Discussion

Under constant carrier gas flow rates, NO₂(g), *N*_C, concentrations are directly proportional to net desorption rates, *R* = *k*_d −

Figure 1. Schematic diagram of the experimental setup: (1) photolysis cell (see Figure 2); (2) reflective reaction chamber; (3) pen-ray UV lamps emitting at $\lambda_{\text{max}} \sim 313$ nm; (4) circulating cryostat; (5) computer workstation; and (6) zero air carrier gas. The Berkeley laser-induced fluorescence NO₂ instrument.³⁰ A frequency doubled YAG laser (YAG) pumps a dye laser (DL), whose output (585 nm) is sampled by fused silica beam splitters to monitor power, frequency, and line width (via Etalon E). Photodiode detectors (PD) monitor beam power. A dispersion prism (DP) selects 585 nm light from the beam, and directs it to a multipass White detection cell (WC), whose pressure is monitored with a 100 Torr Baratron capacitance manometer (B). NO₂ fluorescence is detected by a cooled PMT after being filtered through FC.

$[N_T]$, i.e., to the difference between primary photochemical production rates, J , minus the rates of accumulation, $\partial[N_T]/\partial t$, and chemical, C , or photochemical, D , destruction, of trapped NO₂, N_T :

$$R = k_d[N_T] = J - \partial[N_T]/\partial t - C - D = [N_G]F_C \quad (4)$$

Considering that the LIF detection zone is at 293 K, and $F_C = 41.7 \text{ cm}^3 \text{ s}^{-1}$, the detection of 1 pptv N_G (1 part in 10¹² per

volume = $2.5 \times 10^7 \text{ molecule cm}^{-3}$ at 1 atm, 293 K) in this experimental setup is equivalent to the net release of $R = 1.0 \times 10^9 \text{ N}_G \text{ molecules s}^{-1}$, or $3.4 \times 10^6 \text{ N}_G \text{ molecules cm}^{-2} \text{ s}^{-1}$, from the illuminated area.

Since the incident photon flux is $I_i = 3.0 \times 10^{15} \text{ photons cm}^{-2} \text{ s}^{-1}$, and the primary quantum yield of NO₂ production in ice is $\phi_1 \sim 2 \times 10^{-3}$ over this temperature range,^{17,29} the detection of ~ 10 pptv N_G at peak production from 50 mM NaNO₃ frozen layers (Figure 3a) would imply that about 0.6% of the incident light is absorbed by nitrate: $(10^4 \text{ pptv}) \times (3.4 \times 10^6 \text{ N}_G \text{ molecules cm}^{-2} \text{ s}^{-1}) / (3.0 \times 10^{15} \text{ photons cm}^{-2} \text{ s}^{-1}) / (2 \times 10^{-3}) = 5.7 \times 10^{-3}$, at steady state, if $C = D = 0$. The fact that this fraction is 10 times larger than the actual absorbance of our $\sim 150 \mu\text{m}$ thick frozen 50 mM nitrate layers— $(7.5 \text{ M}^{-1} \text{ cm}^{-1}) \times (5 \times 10^{-3} \text{ M}) \times (0.015 \text{ cm}) = 5.6 \times 10^{-4}$ —proves that peak N_G release rates in these thermograms do not represent instantaneous photochemical production rates, but reflect nonstationary conditions in which N_T accumulated during the course of the experiment is largely desorbed in the final stages. Therefore, the effective rate and quantum yield of N_G release are expected to be, in general, significantly smaller than the rate and quantum yield ϕ_1 of N_T production via reaction 1,^{17,29} depending on the morphology of the layer. The latter will determine the rate constant of N_T desorption, k_d , and, hence, the extent of secondary NO₂ losses.

Accordingly, the $[N_G]$ vs T dependences shown in Figure 3a–f are not expected to be exclusively, or largely, determined by the temperature dependence of J , which primarily arises from the monotonic, exponential temperature dependence of ϕ_1 ,^{17,29} but also from the existence of metamorphic transitions via $k_d(T)$, and, as appropriate to transient phenomena, from H and $[\text{NO}_3^-]$ as well. It is apparent that the upward inflection observed in $[\text{NO}_2]$ at ca. -8°C for $[\text{NO}_3^-] = 50 \text{ mM}$, $H = 0.7^\circ\text{C min}^{-1}$ (Figure 3a) gradually disappears at lower $[\text{NO}_3^-]$. Emission rates sharply decrease above ca. -4°C , following the depletion of accumulated N_T due to an artifact: thawed solutions fall to the QS bottom where they receive less radiation than as NDI's.

Previously, we rationalized similar observations by assuming that photogenerated N_T lines the microscopic cavities of polycrystalline ice before desorbing into the gas phase. The fraction of N_G filling the network of cavities connected to the atmosphere diffuses/effuses away concomitantly with photolysis, while the rest remains occluded in closed pockets until they open up during the softening of the ice matrix at higher temperatures. The existence of N_T and the heterogeneous mechanism underlying the sharp transitions observed in the thermograms is confirmed by decoupling photolysis and desorption: in the experiments shown in Figure 4a,b $[\text{NO}_3^-] = 50 \text{ mM}$ NDI's were illuminated for 3 h at -30°C , and then heated at $H = 0.70^\circ\text{C min}^{-1}$ in the dark. The protracted approach to a steady-state value of ~ 6.5 pptv N_G under isothermal conditions, vs the relatively fast responses observed in the thermograms at low temperatures (see Figure 7b below), suggests that the system is reaching equilibrium via a slow chemical reaction. N_G emissions rapidly fall off after photolysis and display a distinctive surge at ca. -8°C in the dark, analogous to that observed in the bright thermogram of Figure 3a. A similar isothermal experiment at $[\text{NO}_3^-] = 2 \mu\text{M}$, -30°C is shown in Figure 5a,b. In this case, average ~ 240 pptv N_G emissions during 3.2 h amount to the release of $\sim 3 \times 10^{15}$ NO₂ molecules, or to the photolysis of $\sim 50\%$ of the nitrate contained in $\sim 5 \text{ cm}^3$ of $2 \mu\text{M}$ NaNO₃. In contrast to the results of Figure 4a, the slow decline of N_G emissions during the experiment shown in Figure 5a reflects the gradual depletion

Figure 3. (a) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 50 mM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$. (b) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 10 mM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$. (c) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 1 mM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$. (d) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 0.2 mM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$. (e) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 30 μM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$. (f) $\text{NO}_2(\text{g})$ concentration vs temperature during irradiation of frozen 2 μM aqueous nitrate under $H = 0.70^\circ\text{C min}^{-1}$.

of nitrate. Notice that if N_G emissions were directly proportional to $[\text{NO}_3^-]$, as expected for a system in which all processes were first order in (N_T , N_G), the limiting N_G value for $[\text{NO}_3^-] = 50$ mM should be $0.24 \text{ ppbv} \times (50 \text{ mM}/2 \mu\text{M}) = 6 \text{ ppmv}$, rather than 6.5 ppbv as observed.

Evidence that nitrate photolysis and N_T desorption are not the only relevant processes in this system is provided by the fact that the total amount of NO_2 , $\Sigma_N = \int [N_G] F_C dt$, released over the course of a photochemical experiment is proportional to $[\text{NO}_3^-]^{1/2}$ at $H = 0.70^\circ\text{C min}^{-1}$ (Figure 6). Since desorption

Figure 4. (a) NO₂(g) concentrations above frozen 50 mM aqueous nitrate irradiated at $-30\text{ }^{\circ}\text{C}$ for 3 h and then warmed at $H = 0.70\text{ }^{\circ}\text{C min}^{-1}$ in the dark. (b) A blowup of part a after 3 h.

could only delay N_G emissions, and all NDI samples are optically thin, i.e., absorb less than 1% of the incident photon flux (see above), photolysis rates, J , and, hence, Σ_N should increase linearly with $[\text{NO}_3^-]$, in the absence of loss processes with higher than first-order NO₂ dependences, at variance with the results of Figure 6. Clearly, the $\Sigma_N \propto [\text{NO}_3^-]^{1/2}$ dependence cannot originate, solely, in the secondary photolysis of NO₂, another complicating feature considered below in more detail.

The second-order hydrolytic disproportionation of NO₂, reaction 5

has the required stoichiometry to produce the observed $\Sigma_N \propto [\text{NO}_3^-]^{1/2}$ dependence. Equilibrium constants, $K_5(T)$, can be calculated from $\Delta H_5 = -106.7\text{ kJ mol}^{-1}$ and $\Delta S_5 = -278.7\text{ J K}^{-1}\text{ mol}^{-1}$.³² Let us estimate the equilibrium N_G pressure, P_{NO_2} , in reaction 5 at the eutectic, the minimum temperature at which H₂O(l) is present as a macroscopic phase. At the eutectic point, $T = 255\text{ K}$, and $K_5 = 2.2 \times 10^7$ (in M, atm units), 5.9 M NaNO₃ (45.5 M H₂O) is in equilibrium with pure ice and NaNO₃(s).³³ An upper limit to NO₂(aq) concentrations can be obtained from the difference between the expected and observed N_G emissions in Figure 5a (see above), and the stoichiometry of reaction 5: $[\text{NO}_2^-] < 0.2 [\text{NO}_3^-] \sim 1\text{ M}$. Therefore, $P_{\text{NO}_2}(\text{atm}) < 8 \times 10^{-5} [\text{H}^+]$. Assuming pH > 5.0, we find that P_{NO_2}

Figure 5. (a) NO₂(g) concentrations above frozen $2\text{ }\mu\text{M}$ aqueous nitrate irradiated at $-30\text{ }^{\circ}\text{C}$ for 3.25 h, and then warmed at $H = 0.70\text{ }^{\circ}\text{C min}^{-1}$ in the dark. (b) A blowup of part a after 3.25 h.

Figure 6. Total NO₂(g) amounts released during the photolysis of frozen aqueous nitrate solutions warmed at $H = 0.70\text{ }^{\circ}\text{C min}^{-1}$ vs $[\text{NO}_3^-]$. Total amounts are normalized to those measured in frozen 50 mM nitrate.

could not exceed 0.8 ppbv at 255 K. The $P_{\text{NO}_2} \sim 0.2\text{ ppbv}$ detected at $-18\text{ }^{\circ}\text{C}$ in the dark thermogram of Figure 5b is, therefore, compatible with the expected value.

The rates of reaction 5 at the low NO₂ concentrations prevalent in the present experiments are expected to be second order in [NO₂].³⁴ Thus, at steady state, eq 4 predicts that $k_5 P_{\text{NO}_2}^2$

Figure 7. (a) NO₂(g) concentration vs temperature during irradiation of frozen 50 mM aqueous nitrate under $H = 0.30$ °C min⁻¹. (b) NO₂(g) concentration vs temperature during irradiation of frozen 50 mM aqueous nitrate under $H = 0.10$ °C min⁻¹.

$\sim J \propto [\text{NO}_3^-]$, or $P_{\text{NO}_2} \propto [\text{NO}_3^-]^{1/2}$, if $D = 0$, and NO₂ hydrolysis were faster than desorption. This limit is eventually approached at sufficiently large $[\text{NO}_3^-]$ values, since desorption rates, $k_d[\text{N}_\text{T}] = k_d H^{-1} P_{\text{NO}_2}$ (H is Henry's constant for NO₂ in water) increase linearly with P_{NO_2} . The new finding is that extensive, relatively fast NO₂ hydrolysis, reaction 4, occurs on ice at least 12 °C below the eutectic point (cf. Figures 4a and 5a).

Since the time required to sweep the entire temperature range (from -30 °C to above melting) is inversely proportional to the heating ramp, H , Σ_N should be, barring secondary losses, directly proportional to H^{-1} in experiments performed at constant $[\text{NO}_3^-]$. Panels a and b of Figure 7 show thermograms performed on $[\text{NO}_3^-] = 50$ mM NDI at $H = 0.30$ and 0.10 °C min⁻¹, respectively. These results, in conjunction with those of Figure 3a for $H = 0.70$ °C min⁻¹, as well as those performed on $[\text{NO}_3^-] = 2$ μM NDI (not shown), are presented in Figure 8. It is apparent that Σ_N vs H^{-1} plots are not linear: Σ_N only increases about 3-fold upon a 7-fold extension of photolysis time. The larger NO₂ deficits incurred under the slower heating ramps imply that N_T desorption becomes more favorable than chemical and/or photochemical loss reactions at higher temperatures. Thus, NO₂ production is not only a function of T

Figure 8. Total NO₂(g) amounts released during the photolysis of frozen aqueous nitrate solutions as function of the reciprocal of the heating rate H : (▽) $[\text{NO}_3^-] = 2$ μM and (Δ) $[\text{NO}_3^-] = 50$ mM.

and $[\text{NO}_3^-]$, but also of the thermal history of the irradiated sample in these time scales. The molar absorptivity of NO₂(g), averaged over the output of our lamps, is ~ 28 times larger than that of NO₃⁻.²⁹ If trapped NO₂ spent a small fraction of the time as N_G rather than as N_T, the larger quantum yield of NO₂(g) photolysis

$\phi_6 \sim 1$ vs $\phi_1 \sim 8\phi_2 \sim 2 \times 10^{-3}$, would make reaction 6 dominate the NO₂ photodecomposition lifetime. Slow chemical losses due to secondary radical reactions may also contribute to the nonlinearity of the plots of Figure 8.^{28,29}

Implications for Snowpack Chemistry in Polar Regions

The NO₃⁻ concentrations measured in snow at rural and remote sites range from 1 to 20 μM.^{5,51–54} These overlap with the lower $[\text{NO}_3^-]$ range of the present experiments. Considering that nitrate samples were subjected to photon irradiances and temperatures of environmental relevance, our results can be used to interpret NO₂ emissions from sunlit snowpacks. Chu and Anastasio have recently compared the results of laboratory studies on the photochemistry of frozen nitrate solutions with field measurements of NO_x gases released during spring at various high-latitude locations.¹⁷ Their analysis involves equating NO₂ release rates with the $\cdot\text{OH}$ production rates measured using benzoic acid as a $\cdot\text{OH}$ scavenger, as expected from the stoichiometry of reaction 1. Present experiments demonstrate that this cannot be the case because NO₂ desorption from polycrystalline ice is not instantaneous. While trapped in the ice, NO₂ is irreversibly transformed into other species through various pathways. Therefore, the apparent agreement between field NO₂ emissions and the estimates made in ref 17 on the basis of $\cdot\text{OH}$ production rates in the photolysis of NDI is probably fortuitous. We suggest, however, that agreement still would be possible if the species resulting from the decay of NO₂ in ice, such as NO and NO₂⁻/HONO, were eventually released into the boundary layer, and therefore accounted for as NO_x. The $\Sigma_\text{N} \propto [\text{NO}_3^-]^{1/2}$ dependence provides a possible rationalization, at least in part, for the fact that noontime NO_x fluxes emitted from snowpacks, R_{NO_x} , only increase from $R_{\text{NO}_x} \sim 2.5 \times 10^8$ molecule cm⁻² s⁻¹ at $30 \leq [\text{NO}_3^-]/\text{ng g}_{\text{ice}}^{-1} \leq 100$ over Neumayer Station, Antarctica,⁵⁷ to $R_{\text{NO}_x} \sim 5 \times 10^8$ molecule cm⁻² s⁻¹ at $350 \leq [\text{NO}_3^-]/\text{ng g}_{\text{ice}}^{-1} \leq 560$ at the Alert station, Canada.⁸

Conclusions

The dependence of NO₂ emission rates on nitrate concentration and heating rates in the temperature-programmed photolysis of nitrate-doped polycrystalline ice demonstrates that photogenerated NO₂ undergoes extensive chemical and photochemical losses prior to desorption under typical conditions. The hydrolytic disproportionation of photogenerated NO₂ into nitrate and nitrite is the dominant dark loss pathway in ice, even at subeutectic temperatures.
