Received: July 23, 1997; In Final Form: September 17, 1997[®]

The first kinetic measurements for aqueous $[\text{NH}_3\text{OH}]\text{NO}_3$ that are based on species concentrations at hydrothermal conditions are discussed. The decomposition rate of 0.1 and 0.2 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$ was determined in real time by flow-cell IR spectroscopy at 463–523 K and 27.5 MPa. The loss of NH_3OH^+ (2730 cm^{-1} bending combination) and formation of N_2O (ν_3 at 2230 cm^{-1}) occur at the same rate under these conditions and were fit to a first-order rate expression. Using all of the data, $E_a = 103 \pm 21$ kJ/mol and $\ln(A/s) = 21 \pm 5$. The decomposition rate resembles that of solid $[\text{NH}_3\text{OH}]\text{NO}_3$ in a similar temperature range, but the kinetics for dilute solutions and the solid state are too slow to apply to the combustion rate of a more concentrated solution of $[\text{NH}_3\text{OH}]\text{NO}_3$.

Introduction

A highly concentrated aqueous solution of hydroxylammonium nitrate, $[\text{NH}_3\text{OH}]\text{NO}_3$, mixed with alkylammonium nitrate salts burns very rapidly, which makes it useful as a liquid propellant.^{1–3} In fact, even approximately 40 wt % of $[\text{NH}_3\text{OH}]\text{NO}_3$ in water (5 M) will burn steadily provided that the pressure is greater than 5 MPa.⁴ A phenomenological model describing this deflagration process has been developed.⁵ The controlling event is believed to be the rate of decomposition of $[\text{NH}_3\text{OH}]\text{NO}_3$ in the condensed phase. Therefore, the kinetics and pathway of decomposition in water at high temperature and pressure are of interest. The main problem is, however, that the reaction is highly exothermic, which makes it difficult to control during the investigation. Thus, although $[\text{NH}_3\text{OH}]\text{NO}_3$ dissolves up to 95 wt % in water,⁶ the use of a dilute solution has been necessary to measure the reaction rate.

Recent development of spectroscopy/flow cells suitable for real-time IR and Raman studies at hydrothermal conditions ($T = 450\text{--}620$ K, $P = 27.5$ MPa) make direct spectrokinetic measurements now feasible.^{7–9} Described herein is a real-time investigation of the decomposition rate of 0.1 and 0.2 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$ ($m = \text{mol/kg of H}_2\text{O}$) at 463–523 K and 27.5 MPa.

Experimental Section

Within 2 h of use, solutions having 1:1 $\text{NH}_2\text{OH}:\text{HNO}_3$ were prepared from a stock solution of approximately 50 wt % (16.5 M) hydroxylamine (Howard Hall Division of R.W. Greef and Co.), 70 wt % (15.8 M) nitric acid (Fisher Scientific, ACS), and HPLC-grade water and were stored in a glass container. The flow reactor used⁷ permits excellent control of the pressure (± 0.1 MPa), temperature (± 1.5 K), and flow (± 0.01 mL/min, pulseless). The data were collected with a PC that was programmed to control the flow reactor automatically. Such automation permitted multiple data sets to be collected which revealed their overall consistency.

The reaction takes place inside the heated spectroscopy cell constructed of 316 stainless steel (SS) and fitted with sapphire windows.⁷ The cell was sealed by compression against a set of gold gaskets whose thickness also controlled the path length (0.0030–0.0045 mm). These seals have limited durability

primarily due to the stress of temperature cycling and required occasional disassembly and resealing. The reaction zone of the cell had an internal volume of 0.0604 mL as determined by the cylindrical channel machined through the cell body and the flat duct between the sapphire windows. A transport model of the cell indicated laminar flow and that the solution reaches 85% of the cell temperature well within the first 15% of the entrance tube.⁹ The cell/reaction temperature was determined by a K-type thermocouple located in the cell body near the flat duct between the windows.

Experiments were conducted on two concentrations of $[\text{NH}_3\text{OH}]\text{NO}_3$ at 27.5 MPa and with flow rates of 1.79–0.03 mL/min, which resulted in residence times of 2–110 s. A 0.20 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$ solution was studied at four temperatures between 463 and 493 K and 0.10 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$ was studied at seven temperatures between 463 and 523 K. IR spectra (32 summed interferograms, 4 cm^{-1} resolution) were collected with a Nicolet 60 SX FTIR spectrometer using 17 different flow rates at each temperature. After each spectral set was collected and the flow rate was adjusted, the system was stabilized and flushed with at least 10 reactor volumes of sample at the new conditions prior to collection of the next spectral set. Collection of data at each set of flow rates was repeated three times before moving to the next temperature. The cell required resealing after the data sets at the lowest four temperatures were collected on 0.10 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$. A replicate data set was collected at 493 K with the refurbished cell for comparison with the data collected earlier.

Results

Reduction of the spectra to kinetic data required several steps. First, each reaction spectrum was ratioed against the spectrum of pure H_2O in the same cell at the same pressure and temperature to remove as much of the absorption by water as possible. Second, the reactant and product bands were resolved, and areas were calculated by using curve-fitting software (Peakfit, Jandel). The absorbances of interest were fitted with a four-parameter Voigt function. This method permitted accurate integration of the weaker absorptions with the rather poor baselines frequently encountered in IR spectra of water solutions. Third, the absorbances were converted into concentrations at each condition so that the reaction rate could be obtained.

Two distinct absorptions of $[\text{NH}_3\text{OH}]\text{NO}_3$ were observed in the 1800–2900 cm^{-1} window available with sapphire and water.

Figure 1. Example infrared spectra of 0.1 *m* [NH₃OH]NO₃ at 493 K and 27.5 MPa showing the conversion of the NH₃OH⁺ ion (−NH₃⁺ bending combination) into N₂O(aq) as a function of the residence time.

Figure 2. Concentrations of NH₃OH⁺ and N₂O as a function of residence time from 0.1 *m* [NH₃OH]NO₃ at 493 K under 27.5 MPa. Points represent the average of three data sets, and error bars were determined from the sample standard deviation.

The weak, broad absorption at about 2730 cm^{−1} resulted from the −NH₃⁺ bending combination mode of the hydroxylammonium ion reactant.¹⁰ A stronger absorption at about 2230 cm^{−1} is the ν₃ stretch of the aqueous N₂O product (Figure 1). The concentrations represented by the integrated band areas were calibrated internally at each temperature.¹¹ Over most of the temperature range used, the spectra at the shortest residence times indicated no significant reaction and provided an absorbance value for the initial concentration of NH₃OH⁺. The absorbance intensity was converted to concentration by assuming Beer's law. In the highest two temperature sets, some decomposition was evident even at the shortest residence times and was taken into account in the analysis. The N₂O concentration was calibrated similarly from the 2230 cm^{−1} band by the fact that complete reaction was achieved at most temperatures in the longest residence time spectra as indicated by the unchanging area of the N₂O band and the absence of the reactant band. Complete reaction was not achieved at the lowest three temperatures, so the area of the N₂O band at completion at a higher temperature was adjusted to account for the density difference of water and then was set equal to the band area at lower temperature. At completion the N₂O concentration is 0.8 of the initial [NH₃OH]NO₃ concentration based on the stoichiometry determined by Raman spectroscopy at hydrothermal conditions.⁸

Figure 3. Example of first-order rate plots for the conversion of [NH₃OH]NO₃ under 27.5 MPa from the N₂O data at the temperatures shown (see text). Error bars have been omitted for clarity.

TABLE 1: First-Order Rate Constants for NH₃OH⁺ Decomposition and N₂O Formation from Aqueous [NH₃OH]NO₃

expt ^a	<i>T</i> , K	<i>k</i> , s ^{−1} (× 10 ³)	
		NH ₃ ⁺ bend combination	ν ₃ (N ₂ O)

3	523	58 ± 43	43.5 ± 4.5

^a 1: [NH₃OH]NO₃₀ = 0.20 *m*; initial seal of cell. 2: [NH₃OH]NO₃₀ = 0.10 *m*; initial seal of cell. 3: [NH₃OH]NO₃₀ = 0.10 *m*; second seal of cell.

The collection of multiple data sets permitted determination of the uncertainties in the concentration–time data. Attention was given to the propagation of these uncertainties throughout the kinetic analysis. Each group of three flow rate sets at a particular temperature essentially represented a separate kinetic experiment. Thus, the average concentration ($\bar{x}$) at each flow rate was determined from the three individual measurements, and the uncertainty was determined by the sample standard deviation (*s*). The averaged concentration data and resulting uncertainties were then plotted against the residence time which was calculated by dividing the reactor volume given above by the flow rate. The reaction profiles result, such as are shown in Figure 2. The flow rate was corrected for the difference in the density of water at each temperature.

The N₂O concentration was converted to conversion of [NH₃OH]NO₃ by [NH₃OH]NO₃₀ − ([N₂O]/0.8), and the kinetic analysis was performed separately on the reactant and the product data using both zeroth- and first-order rate equations. Zeroth-order plots of concentration vs time and first-order plots of ln(concentration) vs time were constructed up to approximately 60% conversion. The first-order plots are shown in Figure 3. The rate parameters were determined from the slope of weighted-least-squares regression (WLSQR) of the averaged concentration data weighted by their uncertainties. In the first-order kinetic analysis, uncertainties were translated into log space as *s*/ $\bar{x}$.¹² The values of *k* and the resulting uncertainties are listed in Table 1.

Figure 4. An Arrhenius plot of all of the rate constants in Table 1.

The Arrhenius plot of the first-order rate parameters is shown in Figure 4. The WLSQR of the rates of disappearance of NH_3OH^+ and the appearance of N_2O were both calculated at the 95% confidence interval. The error bars assigned to each rate constant on the Arrhenius plot represent the precision of the individual rate measurements and do not represent the uncertainty in their accuracy. The uncertainty of the rate at each temperature is better represented by the uncertainties of the slope and intercept of the WLSQR of all the data shown in the Arrhenius plot.

Reaction Pathway. Extensive work has been devoted to learning about the mechanism of the reactions of $[\text{NH}_3\text{OH}]\text{NO}_3$ in aqueous solution.^{3,8,10,13–26}

The limiting stoichiometry of (1) generally describes a 1:1 ratio of NH_2OH and HNO_3 .^{13–15} At 420–470 K under 27.5 MPa pressure, the Raman scattering intensities of N_2O and NO_3^- in 0.87–1.74 *m* $[\text{NH}_3\text{OH}]\text{NO}_3$ are consistent with the slightly different stoichiometry of (2).⁸ It is known, however, that both the limiting stoichiometry and the reaction details depend on the conditions of the experiment.¹⁴

The details of the NH_2OH – HNO_3 reaction have mainly been probed with a low concentration of NH_2OH in the presence of a large excess of HNO_3 .^{14,16–21} This condition enables the reaction to be investigated at 273–308 K and minimizes the amount of heat released. It is generally agreed that both HNO_3 and HNO_2 competitively oxidize NH_2OH by reactions 3 and 4.

Reaction 3 is most important at small $\text{NH}_2\text{OH}:\text{HNO}_3$ ratios, whereas (4) is increasingly prevalent as this ratio increases.^{17,19} The decomposition of $[\text{NH}_3\text{OH}]\text{NO}_3$ is accelerated by the formation of HNO_2 .^{14,17,18,23} Nonlinear behavior in the form of two stationary reaction states also occurs at small $\text{NH}_2\text{OH}:\text{HNO}_3$ ratios.²⁰ Additional mechanism details have been provided by ^{15}N and ^{18}O isotopic labeling studies.^{23–26}

As a result of maintaining the $\text{NH}_2\text{OH}:\text{HNO}_3$ ratio at one in the current work, a mechanism analysis in the sense of most previous work was not conducted. Also, the behavior of only

two variables, the reactant NH_3OH^+ and product N_2O , are observable in the 1800–2900 cm^{-1} spectral window available (Figure 1). On the other hand, a 1:1 ratio of $\text{NH}_2\text{OH}:\text{HNO}_3$ has the widest practical application.^{1–3}

A pathway of the decomposition of $[\text{NH}_3\text{OH}]\text{NO}_3$ in water leading to (1) is given by reactions 5–8.¹⁷

Steady-state treatment of HNO , HNO_2 , and NH_2OH yields the rate equation (9).

$$-\frac{d[\text{NH}_3\text{OH}]}{dt} = \frac{2k_1k_2}{k_{-1} + 2k_2}[\text{NH}_3\text{OH}][\text{NO}_3] \quad (9)$$

The decreasing bulk dielectric constant of H_2O with increasing temperature²⁷ favors the right side of eq 5, i.e., k_1 increases relative to k_{-1} as the temperature increases. If $k_{-1} \ll k_2$, then eq 9 reduces to $k_1[\text{NH}_3\text{OH}][\text{NO}_3]$. For the special case of $[\text{NH}_2\text{OH}] = [\text{HNO}_3]$, the rate is expected to have apparent first-order behavior in $[\text{NH}_3\text{OH}]\text{NO}_3$. The same expression applies to $d[\text{N}_2\text{O}]/dt$. In Figure 2 the profiles for depletion of NH_3OH^+ and formation of N_2O derived from the IR absorbances closely track one another. The incompleteness of the mechanism (5)–(8) at other conditions is evident, however, when excess NH_2OH or HNO_3 is added. For $\text{NH}_2\text{OH}:\text{HNO}_3$ of 1.0:0.5, the rate indeed decreased by about 0.5, as expected. A 1:2 ratio, however, increased the rate by much more than 2 (i.e., about 10 ± 3). These results are qualitatively consistent with the role of a catalytic species, such as HNO_2 , whose concentration increases as the HNO_3 concentration increases.¹⁹

Arrhenius Kinetics. The activation energy, E_a , for reaction 3 was reported to be 107 kJ/mol from the temperature rise during reaction in the 289–308 K range.¹⁴ E_a for (4) was estimated¹⁴ to be 65 kJ/mol at 273–298 K from the rate of change of the UV absorbance of NO_2^- . More recently, the time-to-reaction method based on thermal explosion theory was applied to aqueous solutions of $[\text{NH}_3\text{OH}]\text{NO}_3$ at 420–470 K under 27.5 MPa.⁸ The results indicated $E_a = 129 \pm 29$ kJ/mol for 0.76–1.52 *m* solutions and $E_a = 66 \pm 8$ kJ/mol for 1.58–1.74 *m* solutions. The initial stage of gas evolution from solid $[\text{NH}_3\text{OH}]\text{NO}_3$ is described by eq 10,²⁸ where E_a is in kJ/mol.

$$k(\text{s}^{-1}) = 10^{4.6} e^{-69/RT} \quad (10)$$

Isothermal measurements of species concentrations are difficult to conduct with $[\text{NH}_3\text{OH}]\text{NO}_3$ because of the rapid formation of heat during the reaction. To succeed in the current work, it was necessary to use ≤ 0.2 *m* solutions because the heat generated was sufficiently small so as to be controlled by the cell. The concentration–time profiles for which Figure 2 is representative provide rates of conversion in the 463–523 K range. These data fit the first-order rate expression of eq 9 as is shown in Figure 3. It was found, however, that a zeroth-order rate plot gave a statistically equivalent fit. Zeroth-order behavior could be rationalized by assuming that the decomposition of $[\text{NH}_3\text{OH}]\text{NO}_3$ is mainly wall-catalyzed. However, a previous decomposition study of $[\text{NH}_3\text{OH}]\text{NO}_3$ in the hydro-

thermal regime revealed only a small difference in the rate in a 316 SS cell compared to a Ti cell.⁸ This result suggests that wall catalysis is not a major factor, which makes zeroth-order kinetics a less appropriate description for the hydrothermal regime. Alternatively, the complexity of the rate constant in eq 9 may be responsible for the absence of a simple order behavior. We have no method to probe the individual steps of (5)–(8) in the hydrothermal regime.

Table 1 lists the first-order rate constants treated statistically as discussed above. The precision in the rate constants is generally satisfactory, but it is apparent that an uncertainty of a factor of 2 or less exists in the accuracy on the basis of the differences incurred when the cell was dismantled and reassembled. This degree of uncertainty in the accuracy of rate constants is in line with our past experience in reaction rate measurements at hydrothermal conditions.^{7,8,29} A possible explanation is that flow-rate changes occur from an occasional phase separation (bubble) somewhere in the flow path. A phase separation did not take place in the observation region because no gaseous N₂O was detected.

Figure 4 shows the Arrhenius plot for NH₃OH⁺ destruction and N₂O formation. The rates of these processes were statistically indistinguishable and are, therefore, included together on the same plot. The resulting values of $E_a = 103 \pm 21$ kJ/mol and $\ln(A/s) = 21 \pm 5$ are obtained. This value of E_a lies close to that previously estimated for reaction 3 at 292–308 K,¹⁴ but no preexponential factor was previously available. It is also in the range of 129 ± 29 kJ/mol given previously based on the thermal explosion method for <1.5 M solutions of [NH₃OH]NO₃.⁸ These results suggest that the components of [NH₃OH]NO₃ react by (3), itself a complex process, and that (3) controls the overall rate. At higher concentrations of [NH₃OH]NO₃, the autocatalysis, possibly by the HNO₂ thus formed, accelerates the rate of reaction and release of heat, giving a lower apparent activation energy, i.e., 66 ± 8 kJ/mol.⁸

Relation to Combustion. Some of the mechanistic and kinetic details discussed above appear to apply to very concentrated solutions and to solid [NH₃OH]NO₃.^{10,22,23,28,30} In particular, accelerating rate observed is consistent with autocatalysis. A type of nonlinear behavior is also noted in the formation rate of the decomposition gases from pyrolysis of >12 M solutions of [NH₃OH]NO₃ upon flash heating under 3.5 MPa of Ar.¹⁰ At high concentrations, however, the gaseous products frequently include N₂, NO, and NO₂,^{10,22,23,30} but the latter two products can form by various secondary reactions in mixtures containing HNO₂ and HNO₃.³¹ The activation energy for solid [NH₃OH]NO₃ (eq 10)²⁸ resembles that for eq 4,¹⁴ which is consistent with the catalytic role of a species such as HNO₂. The rate constant of eq 10 and the kinetics determined in this article are the same at 408 K, which is reasonable on the basis of the roughly similar temperature range in which they were measured.

From the practical point of view, however, it is useful to know whether the kinetics of reaction 2 for a dilute solution or eq 10 for solid [NH₃OH]NO₃ apply to the combustion of concentrated [NH₃OH]NO₃ solutions. With an estimated surface temperature⁵ of 600 K for a burning solution of 9.1 M [NH₃OH]NO₃, the kinetics of neither eq 10 ($k = 4 \times 10^{-2}$ s⁻¹) nor Figure 4 ($k = 1$ s⁻¹) are fast enough. The model rate constants required to fit the burning rate of 5–9 M [NH₃OH]NO₃ solutions⁵ are in the range of $k = 2 \times 10^4$ – 2.2×10^5 s⁻¹. Thus, we concluded that the rate of decomposition of [NH₃OH]NO₃ is suppressed either by the large excess of H₂O in 0.1–0.2 M [NH₃OH]NO₃ or by the virtual absence of H₂O as in the solid [NH₃OH]NO₃. When the [NH₃OH]NO₃ concentration is low, reaction 4 cannot

dominate, and heat will not be generated at a fast enough rate to sustain burning. In the absence of H₂O, it is possible that the transport properties and concentrations of the key catalytic species are too low to accelerate the rate in the stage of the reaction studied. Only when the [NH₃OH]NO₃ concentration is 5 M or higher do all of the necessary properties for fast reaction become sufficiently optimized to sustain combustion. As a result, the global Arrhenius parameters yielding the appropriate rates to model the combustion process of concentrated [NH₃OH]NO₃ solutions are most likely the result of a different rate-controlling process than exists below 475 K. In any case the Arrhenius parameters for the combustion regime are probably a mixture of transport rates and reaction rates in the heated surface reaction zone.

Acknowledgment. We are grateful for support of this work by the Army Research Office on the URI Project DAAL03-92-G-0174. The sample of hydroxylamine in H₂O was generously supplied by Hugo Galletta of Howard Hall Division, R.W. Greeff & Co.
