Abstract

Several platinum(II) complexes of the general type $[\text{Pt}(\text{OND})\text{X}]$ have been prepared and characterized, the ligand (OND) representing the phenolate anion of the tridentate Schiff bases *N*-(2-diethylaminoethyl)-salicylaldimine ($\text{D} = \text{NEt}_2$), *N*-(2-ethylaminoethyl)-salicylaldimine ($\text{D} = \text{NHet}$) and *N*-(3-thia-*n*-pentyl)-salicylaldimine ($\text{D} = \text{SEt}$) and $\text{X} = \text{Cl}, \text{NO}_3$. As shown by conductimetric studies the nitrate complexes $[\text{Pt}(\text{OND})\text{NO}_3]$ dissociate completely in methanol according to:

Spectrophotometry (normal and stopped-flow) has been used to study the kinetics of solvent substitution according to

with a variety of neutral and anionic nucleophiles *Y* in methanol at 20 °C and constant ionic strength, $I = 0.2 \text{ M}$ (NaClO_4). The substitution follows a one-term rate law, $\nu = k_{\text{obs}}[\text{Pt}(\text{OND})(\text{H}_2\text{O})^+] = k_{\text{Y}}[\text{Y}] \cdot [\text{Pt}(\text{OND})(\text{H}_2\text{O})^+]$. The k_{Y} data obtained for 13 ($\text{D} = \text{NEt}_2$) and 7 ($\text{D} = \text{NHet}; \text{SEt}$) different nucleophiles *Y* cannot be adequately correlated with their n_{Pt}^0 values according to the well-known relationship $\log k_{\text{Y}} = sn_{\text{Pt}}^0 + \log k_{\text{S}}$. The deviations are strongest for large and bulky nucleophiles such as $\text{Y} = \text{Ph}_3\text{P}, \text{Bu}_3\text{P}, \text{Ph}_3\text{As}, \text{I}^-$ and for $\text{D} = \text{NEt}_2$, from which it is concluded that steric crowding hinders the formation of the 5-coordinate transition state. The rate reducing steric *cis*-effect observed is of the order $k_{\text{Y}}(\text{D} = \text{NEt}_2) : k_{\text{Y}}(\text{D} = \text{NHet}) : k_{\text{Y}}(\text{D} = \text{SEt}) = 1 : 35 : 63$ for small nucleophiles *Y* and as large as 1 : 192 : 2640

for $\text{Y} = \text{Ph}_3\text{P}$. The introduction of substituents *X* in the salicylaldehyde ring in *ortho* (X^3), *meta* (X^4) and *para* position (X^5) to the phenolic oxygen proves the existence of rather small electronic effects (X^4, X^5) and much stronger steric effects of bulky substituents X^3 , neighboring the donor oxygen.

With the standard substrate *trans*- $[\text{Ptpy}_2\text{Cl}_2]$ some new n_{Pt}^0 values were determined, namely for *N,N'*-dimethylthiourea ($n_{\text{Pt}}^0 = 7.02$), *N,N'*-diphenylthiourea ($n_{\text{Pt}}^0 = 7.19$), *N,N,N',N'*-tetramethylthiourea ($n_{\text{Pt}}^0 = 6.05$) and for the pseudo-halide dicyanoamide ion, $\text{N}(\text{CN})_2^-$ ($n_{\text{Pt}}^0 = 3.05$). The n_{Pt}^0 value for the pseudo-halide tricyanomethanide ion, $\text{C}(\text{CN})_3^-$, was estimated to be 3.03.

Introduction

Ligand substitution in Pt(II) complexes according to eqn. (1) follows the two-term rate law (eqn. (2))

in which the ligand-dependent contribution $k_{\text{Y}}[\text{Y}]$ (ligand path) is in general much greater than the

$$\text{rate} = (k_{\text{S}} + k_{\text{Y}}[\text{Y}])[\text{L}_3\text{PtX}] = k_{\text{obs}}[\text{L}_3\text{PtX}] \quad (2)$$

solvent-initiated, ligand-independent contribution k_{S} (solvent path). Both pathways are associative (A-mechanism) and the reactivity of the nucleophile *Y* is characterized by its n_{Pt}^0 value [1]. This parameter refers to the standard substrate *trans*- $[\text{Ptpy}_2\text{Cl}_2]$ reacting according to eqn. (1) in methanol at 30 °C and is defined by eqn. (3) [1]:

$$n_{\text{Pt}}^0 = \log(k_{\text{Y}}/k_{\text{S}}') = \log\left(\frac{k_{\text{Y}}[\text{MeOH}]}{k_{\text{S}}}\right) \quad (3)$$

The n_{Pt}^0 values of more than 40 nucleophiles *Y* have been determined and range from 3 ($\text{Y} = \text{Cl}^-$) to 9 ($\text{Y} = \text{Ph}_3\text{P}$), thus demonstrating an enormous spread in nucleophilicity.

The significance of the n_{Pt}^0 scale is evidenced by the finding that in many cases a relationship (eqn.

*This publication presents the main part of the *Dr.-Ing. Thesis* submitted by M.B. to the Technische Hochschule Darmstadt in 1985.

**Author to whom correspondence should be addressed.

(4)) can be successfully applied to describe the reactivity of nucleophiles Y towards Pt(II) com-

$$\log k_Y = s \cdot n_{Pt}^0 + \log k_S \quad (4)$$

plexes other than the standard substrate *trans*-[Ptpy₂Cl₂] [1]. The parameter *s*, which fits rate constant *k_Y* for a given platinum complex to the *n_{Pt}⁰* scale, is called 'nucleophilic discrimination factor'.

The present study was carried out to test the general applicability of eqn. (4) to several new Pt(II) complexes of type I (X = anion) with D representing a NEt₂ group (**Ia**), a NHEt group (**Ib**) or a SEt group (**Ic**).

As shown for the corresponding Pd(II) complex **Ia** (X = Cl; X³ = X⁴ = X⁵ = H) by single crystal X-ray analysis, these complexes have an almost square-planar arrangement of the donor atoms around the metal, the phenyl ring being slightly bent off [2]. The following symbols will be used:

In methanol the nitrate complexes **I** (X = NO₃) dissociate according to eqn. (5) (S = solvent):

Reaction (eqn. (6)) was studied in methanol (*I* = 0.2 M; NaClO₄) at 20 °C for a variety of neutral and anionic nucleophiles Y and for substituted and non-substituted complexes **Ia**–**Ic** by normal and stopped-flow spectrophotometry:

In the course of the study it became necessary to determine the hitherto unknown *n_{Pt}⁰* values for the dicyanoamide anion (N(CN)₂[−]) and for several *N*-alkylated thiourea derivatives according to eqn. (1) (L₃Pt–X $\hat{=}$ *trans*-[Ptpy₂Cl₂]) and eqn. (3).

Experimental

Solvent and Nucleophiles Y

The solvent MeOH (Merck, Darmstadt) was reagent grade and was used without further treatment. The nucleophiles Y applied for the study of the reaction (eqn. (6)) were all commercially available and were either bought in reagent grade quality (Ph–S–Me, thiourea = TU; LiCl; LiBr; NaSCN; [(*n*-Bu)₄N]⁺ I = TBAI; NaN(CN)₂ = NaDCA) or purified by recrystallization (Ph₃P; Ph₃As; *N,N'*-dimethylthiourea = DMTU; *N,N'*-diphenylthiourea = DPTU; *N,N,N',N'*-tetramethylthiourea = TMTU) or by fractional distillation (tri-*n*-butylphosphane = Bu₃P). The NaClO₄ applied for adjusting the ionic strength to *I* = 0.2 M was reagent grade.

Ligands

The tridentate Schiff base ligands were prepared by reacting substituted or non-substituted salicylaldehyde with H₂N–CH₂–CH₂–NEt₂ (Aldrich, Steinheim), H₂N–CH₂–CH₂–NHt (Aldrich, Steinheim) or H₂N–CH₂–CH₂–SEt (as prepared from phthalimide, 1,2-dibromoethane and ethanethiol according to a modified procedure described in the literature [3]). The substituted salicylaldehydes were either commercially available (4-methoxysalicylaldehyde, 5-methoxysalicylaldehyde) or prepared according to standard procedures (5-methylsalicylaldehyde [4], 5-bromosalicylaldehyde [5], 5-iodosalicylaldehyde [6], 5-nitrosalicylaldehyde [7], 3,5-diiodosalicylaldehyde [8], 3-*t*-butyl-5-methylsalicylaldehyde [9]).

The following standard procedure was applied for the formation of the various Schiff bases. A solution of 50 mmol amine in 15 ml EtOH is added to a stirred solution of 49 mmol salicylaldehyde in 100 ml EtOH, whereupon the mixture turns yellow immediately. After 30 min of further stirring at slightly elevated temperature the solution is evaporated to dryness by vacuum distillation, finally at 90 °C, to remove excess amine and water. The residual red-brown, oily Schiff base is reacted with PtCl₂ without further purification.

Complexes

trans-[Ptpy₂Cl₂] was prepared from K₂PtCl₄ according to a standard procedure [10] and characterized by elemental analysis.

The complexes [Pt(OND)NO₃] were prepared by the following standard procedure: 0.8 g PtCl₂ (3 mmol; Degussa, Frankfurt), 0.42 g Na₂CO₃ (4 mmol),

^adec, decomposition.

3 mmol tridentate Schiff base and 35 ml DMSO are heated in a two-neck-flask to 80–85 °C for 30 min under vigorous stirring (the flask is equipped with a cooler and an inner thermometer). After that a small sample of the reaction mixture is withdrawn and added to water; the formation of a yellow precipitate indicates the formation of the complex [Pt(OND)Cl]. The reaction mixture is then filtered, reduced to 10 ml by vacuum distillation and poured into 60 ml of water saturated with NaCl. The yellow precipitate of [Pt(OND)Cl] formed is filtered, washed with water and dissolved in chloroform. The chloroform solution is dried with anhydrous CaCl₂ and evaporated to dryness; the residual chloro complex is recrystallized from EtOH.

To convert the chloro complex [Pt(OND)Cl] into the nitrate complex [Pt(OND)NO₃], 1.75 mmol of [Pt(OND)Cl] are dissolved in slightly warmed EtOH (approx. 100 ml or more, if necessary) and 1.75 mmol solid AgNO₃ are added. The reaction mixture is kept at 40 °C for 30 min in the dark and the precipitate of AgCl formed is then filtered off. The volume of the yellow filtrate is reduced by vacuum distillation and the crystals of pure [Pt(OND)NO₃] formed are filtered off and dried at 80 °C. Further recrystallization from EtOH is not necessary as long as the precipitate of AgCl is coarse enough not to pass the filter upon filtration.

Table I presents the results of elemental analysis. The complexes were additionally characterized by their ¹H NMR spectra, IR spectra and UV–Vis spectra (see Table II).

In the solid state the nitrate complexes [Pt(OND)NO₃] are stable towards air and light. Their methanol solutions, however, should be kept in the dark to avoid slow decomposition. The methanol solutions of [Pt(5-Me-ONNEt₂)NO₃] and [Pt(5-NO₂-ONNEt₂)NO₃] begin to decompose even in the dark after 4–5 h.

UV–Vis Spectra and Conductance Data

The spectra were recorded with a double beam UV–Vis spectrophotometer (Zeiss, type DMR-22 WL, or Perkin-Elmer, type PE 554) in quartz cells.

Conductivity data were obtained with the conductometer type E 365 B (Metrohm) connected to cells with cell constants of 0.805 and 0.673 cm⁻¹. The equivalent conductance of the nitrate complexes [Pt(OND)NO₃] (see Table III) was determined for the concentration range 5 × 10⁻³ to 1 × 10⁻⁴ M. When ligand substitution in *trans*-[PtPy₂Cl₂] by neutral nucleophiles Y was followed conductimetrically the conductometer was connected to a recorder to register the κ/t curves (κ = specific conductance).

Kinetic Measurements

Most of the kinetic runs were monitored spectrophotometrically, either by standard spectrophotometry (reactions with a half life of $t_{1/2} > 1$ min) or by 'stopped-flow' spectrophotometry ($t_{1/2} < 1$ min). The equipment used for the latter technique has been described earlier [11]. The measurement of the absorbance $A = f(t)$ was carried out under pseudo-first-order conditions ($[Y] \gg [\text{complex}]$) at a wavelength with a maximum difference ΔA between initial complex and product (see Table V). Some kinetic runs were monitored conductimetrically (see Table IV).

To evaluate the experimental rate constant k_{obs} a total of approximately 50 A/t or κ/t data points were fitted to the function $(A - A_{\infty})/(A_0 - A_{\infty}) = \exp(-k_{\text{obs}} \cdot t)$ or to the function $(\kappa - \kappa_{\infty})/(\kappa_0 - \kappa_{\infty}) = \exp(-k_{\text{obs}} \cdot t)$ with a computer program based on the least-squares method. The deviation from ideal first-order kinetics was smaller than 2%.

Calculation of the n_{Pt}^0 Values

The n_{Pt}^0 values were calculated on the basis of eqn. (3). Both k_Y and k_S follow from plotting k_{obs}

^aStandard conditions: [complex] = 10⁻⁴ M; [NaClO₄] = 0.2 M; T = 20 °C. ^bData refer to final spectra obtained after addition of an at least 100 fold excess of the nucleophile Y to the nitrato complex [Pt(OND)NO₃].

versus the concentration of entering nucleophile Y, rate constant k_S representing the intercept at [Y] = 0. Especially for very nucleophilic ligands Y (i.e., for $k_Y \gg k_S$) extrapolation to [Y] = 0 produces k_S values with a large error. Therefore, the value $k_S = 6.67 \times 10^{-6} \text{ s}^{-1}$ ($k'_S = 2.7 \times 10^{-7} \text{ M}^{-1} \text{ s}^{-1}$) was taken from the literature [12].

The n_{Pt}^0 values applied for correlating the observed rate constants according to eqn. (4) are those stemming from the pioneering work done by Belluco *et al.* [13] and Pearson *et al.* [12], except for the nucleophile Ph–S–Me ($n_{Pt}^0 = 4.30$ [14]*).

Results and Discussion

UV–Vis Spectra

The absorption data for the nitrato complexes **la**–**lc** as obtained from their methanol solutions in the presence of NaClO₄ (0.2 M) at 20 °C are compiled in Table II together with the spectra resulting in the presence of excess nucleophile Y.

*The n_{Pt}^0 value obtained is slightly smaller than n_{Pt}^0 (Ph–S–Me) = 4.45, which can be derived from the work carried out by Hoover and Zipp [15].

It follows from Table II that the spectra of all substituted and non-substituted complexes [Pt-(OND)X] are very similar indeed. There is one absorption band in the range $\lambda = 290\text{--}305$ nm ($\epsilon \approx 5000\text{--}13\,000$ M⁻¹ cm⁻¹) with a shoulder in the range $\lambda = 305\text{--}320$ nm and another absorption band in the range $\lambda = 385\text{--}410$ nm ($\epsilon \approx 2000\text{--}6000$ M⁻¹ cm⁻¹). The latter one is probably due to a $n \rightarrow \pi^*$ transition at the phenolate oxygen, whereas the others refer to charge transfer and inner ligand transitions. There is practically no absorption beyond $\lambda = 420$ nm and the spectra do not provide any indication for bridged species, which is in agreement with the finding that the corresponding palladium complex [Pd(ONNEt₂)Cl] is monomeric in the solid state [2].

Substituents X⁵ on the aromatic ring clearly affect the lowest energy absorption in the sense that an electron withdrawing substituent such as the nitro group causes a blue shift ($\lambda_{\text{max}} = 354$ nm) and that an electron releasing substituent such as the methoxy group causes a red shift ($\lambda_{\text{max}} = 425$ nm). A simple correlation of λ_{max} with the corresponding Hammett parameters is not possible, however.

Any variation of or at the donor atom D affects neither λ_{max} of the lowest energy absorption (393, 394 and 391 nm for D = NEt₂, NHEt and SEt) nor λ_{max} of the highest energy absorption significantly (290, 291 and 287 nm), which thus proves that any Pt–D charge transfer does not occur in this wavelength range.

The data compiled in Table II were taken as the basis for finding the optimum wavelength for the spectrophotometrically monitored substitution reactions.

Solubility and Dissociation

The nitrate complexes [Pt(OND)NO₃] are easily soluble in acetone, MeOH, EtOH and DMSO, less soluble in *t*-BuOH, water and chloroform and only sparingly soluble in solvents such as benzene and 2,4-dimethylpentanol-3.

Table III presents the data obtained for the equivalent conductance Λ in MeOH at ambient temperature. The values for Λ (corrected for solvent conductance) lie in the range 79–91 Ω^{-1} cm² mol⁻¹. According to Geary's review [16] on conductance data of different electrolytes in MeOH the 1:1 and 1:2 electrolytes produce an equivalent conductance in the range 80–115 and 160–220 Ω^{-1} cm² mol⁻¹, respectively. This means that the nitrate complexes studied (see Table III) behave as 1:1 electrolytes, i.e., dissociate completely. It is of interest to note that the corresponding chloro complexes [Pt(OND)-Cl] dissociate to a much lesser extent.

The complete dissociation of the nitrate complexes according to eqn. (5) raises the question as to what the solvent S really is. Considering the fact

^aConcentration range 5×10^{-3} – 1×10^{-4} M. ^bAveraged values.

that the reagent grade MeOH applied contains residual water ($[\text{H}_2\text{O}]_{\text{max}} = 0.025$ M) the ratio [complex]/[H₂O] is approximately 1:250 and the ratio [H₂O]/[MeOH] corresponds to 1:1250. So, there is much more water than complex and much more methanol than water. If in eqn. (5) the solvent S were MeOH, any increase in the water concentration should shift the equilibrium (eqn. (7)) towards the aquo species [Pt(OND)(H₂O)]⁺:

The kinetic finding, however, that the stepwise increase of the water concentration up to [H₂O] = 0.2 M does not affect the rate of solvent replacement in the species [Pt(ONNEt₂)S]⁺ by iodide ions is very much in favor of the interpretation given by eqn. (8) with water being coordinated instead of methanol:

The more correct description of ligand replacement in the nitrate complexes according to eqn. (6) is therefore given by eqn. (9), with coordinated water being replaced by neutral and anionic nucleophiles Y:

The attempt to isolate the aquo complex as perchlorate [Pt(OND)(H₂O)]ClO₄ was not successful. The product obtained was not uniform, which indicates that in the solid state the formation of the neutral substrate [Pt(OND)X] instead of the salt [Pt(OND)(H₂O)]X is obviously preferred. In addi-

tion, the product obtained upon addition of equivalent amounts of a strong base (NaOH, KOR with R = *t*-Bu) to the methanol solution of [Pt(OND)NO₃] could not be identified as the hydroxo complex [Pt(OND)OH]. Again, the yellow to deep-brown product was not uniform and of low solubility, which is not surprising when one considers the well-known lability of Schiff bases towards strong bases and the tendency of Pt(II) hydroxo complexes to form bridged species.

New *n*_{Pt}⁰ Values

The kinetics of ligand replacement in the standard complex *trans*-[Ptpy₂Cl₂] according to the reaction (eqn. (10)) were studied with several nucleophiles Y, the *n*_{Pt}⁰ values of which are hitherto unknown.

The nucleophiles investigated were the tricyano-methanide ion (C(CN)₃⁻ = TCM⁻)*, the dicyano-

amide ion (N(CN)₂⁻ = DCA⁻), *N,N'*-dimethylthiourea (DMTU), *N,N'*-diphenylthiourea (DPTU) and *N,N,N',N'*-tetramethylthiourea (TMTU).

Even in the presence of a large excess of the anion TCM⁻ in the system *trans*-[Ptpy₂Cl₂]/TCM⁻/MeOH no spectral changes were to be observed within 12 h. This could mean that either the chloride ion is not replaced or the spectra of *trans*-[Ptpy₂Cl₂] and *trans*-[Ptpy₂Cl(TCM)] are very similar. The latter explanation is preferred since the TCM⁻ ion is able to displace water from the complex [Pt(ONNEt₂)(H₂O)]⁺ (see below).

The data obtained for the nucleophiles DCA⁻, DMTU, DPTU and TMTU are compiled in Table IV. One learns that the dicyanoamide anion DCA⁻ is a poor nucleophile with a *n*_{Pt}⁰ value (3.05) very close to that of the chloride ion (3.04). When the nucleophile thiourea (= TU; *n*_{Pt}⁰ = 7.17 [13]) is *N*-alkylated, the change in nucleophilicity is small for *N,N'*-dimethylthiourea (= DMTU; *n*_{Pt}⁰ = 7.02) and *N,N'*-diphenylthiourea (= DPTU; *n*_{Pt}⁰ = 7.19) and more significant (decrease in *k*_Y by a factor of 13) only for *N,N,N',N'*-tetramethylthiourea (= TMTU; *n*_{Pt}⁰ = 6.05). It could well be that the fourfold methylation of

*The salt K[C(CN)₃] = KTCM was prepared as described in the literature [17].

thiourea causes steric crowding in the transition state.

Kinetics of Ligand Substitution in the Complexes [Pt(OND)NO₃]

As discussed above the nitrato complexes [Pt(OND)NO₃] dissociate completely in MeOH to form the cationic aquo species [Pt(OND)(H₂O)]⁺.

It is well known that the rate of reactions between cationic and anionic species decreases with increasing ionic strength. It was not surprising, therefore, to find for the substitution reaction (eqn. (11)) (Y⁻ = I⁻, Cl⁻) a non-linear relationship between

the experimental rate constant k_{obs} and the anion concentration [Y⁻]. At higher concentration of Y⁻ (i.e., at higher ionic strength of the medium) the values obtained for k_{obs} became apparently smaller than expected according to the relationship $k_{\text{obs}} = k_Y[\text{Y}^-]$. To avoid this effect the ionic strength of the medium was adjusted to $I = 0.2$ M with NaClO₄ and this standard condition was maintained throughout all kinetic experiments.

Fig. 1. The dependence of rate constant k_{obs} on the excess concentration of the entering nucleophile Y for solvent substitution in the complex [Pt(ONNEt₂)(H₂O)]⁺ at 20 °C in methanol ($I = 0.2$ M (NaClO₄); TU = thiourea).

Figure 1 presents some typical data obtained for replacement of water in the species [Pt(ONNEt₂)(H₂O)]⁺ by the nucleophiles Br⁻, SCN⁻ and TU (= thiourea) under standard conditions ($I = 0.2$ M; $T = 20$ °C; [complex] = 10^{-4} M). In all cases the time dependence of the change in absorbance can be fitted to a single exponential function (see 'Experimental') and the experimental rate constant k_{obs} increases linearly with the concentration of the nucleophile according to the rate eqn. (12). Rate constant k_Y is obtained from the slope of the curves shown in Fig. 1 by least-squares fitting. The finding rate = $k_{\text{obs}}[\text{complex}] = k_Y[\text{Y}][\text{complex}]$ (12)

that there is no intercept (i.e., no solvent path) corresponds convincingly to the fact that the nitrato

Fig. 2. The dependency $\log k_Y = f(n_{\text{Pt}}^0)$ for solvent substitution in the complex cation [Pt(ONNEt₂)(H₂O)]⁺ (the numbering of the nucleophiles Y corresponds to that in Table V).

complex introduced dissociates to form the solvento species [Pt(ONNEt₂)(H₂O)]⁺. The data obtained for rate constant k_Y are compiled in Table V.

Looking first at water replacement in the aquo complex [Pt(ONNEt₂)(H₂O)]⁺ one recognizes that there is a wide spread in nucleophilicity for the thirteen nucleophiles studied. Rate constant k_Y is smallest for Y = py ($0.683 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$) and largest for Y = TU = thiourea ($531 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$). Figure 2 shows a plot of $\log k_Y$ versus the parameter n_{Pt}^0 with a numbering of the ligands corresponding to that given in Table V. The overall impression is that a linear correlation between $\log k_Y$ and n_{Pt}^0 according to eqn. (4) does not exist. Although seven nucleophiles (1–5, 10, 12) fall nicely on the dashed line corresponding to $s = 1$ (s = nucleophilic discrimination factor; see eqn. (4)), nucleophiles 6–9, 11 and 13 deviate strongly. One could argue, of course, that the n_{Pt}^0 scale refers to the neutral substrate *trans*-[PtPy₂Cl₂] whereas the aquo complex [Pt(ONNEt₂)(H₂O)]⁺ is cationic. It follows from this argument that the equilibrium constant K_{os} for outer-sphere complex formation according to eqn. (13) is certainly

greater for anionic nucleophiles Y⁻ than for neutral nucleophiles Y and that the experimental rate constants $k_Y = k_Y'K_{\text{os}}$ (see Table V) should be corrected for this electrostatic interaction. One can estimate that the ratio $K_{\text{os}}(\text{Y} = \text{anion})/K_{\text{os}}(\text{Y} = \text{neutral})$ is

^aStandard conditions: $I = 0.2$ M (NaClO₄), $T = 20$ °C, $[\text{complex}] = 10^{-4}$ M. ^bWavelength for observation. ^cAs obtained from the slope of the plot $k_{\text{obs}} = k_Y[Y]$ according to eqn. (12) by least-squares fitting. ^dThe kinetic runs were carried out in buffered solution (0.05 M 2,6-lutidine; 0.1 M 2,6-lutidinium perchlorate; 0.1 M NaClO₄).

of the order 3.3–4.0*. The correction for electrostatic effects would mean, therefore, that the experimentally obtained rate constants k_Y for the anions $Y = \text{SCN}^-$, Cl^- , Br^- , I^- (2, 7, 9, 10; see Table V and Fig. 2) have to be divided by a factor of approximately 3.5 to make them compatible with the rate constants obtained for neutral nucleophiles Y. It can be easily seen from Fig. 2 that such a correction reduces the degree of scattering of the data slightly but does not eliminate it.

The fact that eqn. (4) is not able to correlate the rate data satisfactorily has to be due to arguments other than electrostatic. Looking at Fig. 2 the most striking result is the high nucleophilicity of TU, DPTU and DMTU (12, 5 and 4) as compared to the unexpectedly low nucleophilicity of Bu₃P, Ph₃As and Ph₃P (6, 11 and 13). Considering the fact that the ligand replaced in these studies is a water molecule *cis*-coordinated to a phenolic oxygen one could imagine that hydrogen bonding is a rate-increasing factor in the case of thiourea (TU) and its di-alkylated derivatives DPTU and DMTU. All of these three nucleophiles can form N–H···O bonds either with the leaving water molecule (transition state more easily formed) or with the phenolic oxygen (product ground state stabilized). As a matter of fact, the nucleophile TMTU (*N,N,N',N'*-tetramethylthiourea) is not capable of forming this type of hydrogen bond and reacts much slower ($k_Y(\text{TU})/k_Y(\text{TMTU}) = 12:1$).

*The calculation of an outer-sphere complex formation constant K_{os} is carried out according to the expression theoretically deduced by Fuoss [18]:

$$K_{\text{os}} = \frac{4\pi Na^3}{3000} \exp(-U/kt)$$

The interionic potential $U = Z_1 Z_2 e^2 / aD$ as well as K_{os} depend on the parameter a , the distance of closest approach of two ions. For $a = 400$ pm and $a = 600$ pm, the ratio K_{os} ($Z_1 = +1$; $Z_2 = -1$)/ K_{os} ($Z_1 = +1$; $Z_2 = 0$) comes out to be 3.3 and 4.0, respectively.

The finding that the nucleophile $Y = \text{Ph}_3\text{P}$ with one of the highest n_{Pt}^0 values known ($n_{\text{Pt}}^0 = 8.93$) reacts rather slowly with the complex $[\text{Pt}(\text{ONNet}_2)(\text{H}_2\text{O})]^+$ strongly indicates that steric problems are involved. The formation of the five-coordinate transition state is obviously hindered when the bulky ligand Ph₃P (13) approaches the metal carrying the diethyl ammonium group in *cis*-position. The same is probably true for the nucleophiles Ph₃As (11) and Bu₃P (6). If so, the variation of the steric demands of the donor group D should be a good indicator (see below).

Table V also presents the rate data obtained for the reaction of the complex cations $[\text{Pt}(\text{ONNHET})(\text{H}_2\text{O})]^+$ and $[\text{Pt}(\text{ONSET})(\text{H}_2\text{O})]^+$ with a variety of nucleophiles Y. It should be pointed out that water substitution in these two complexes follows rate law (eqn. (12)) as well. As shown in Figs. 3a–3c, qualitatively the patterns of reactivity appear to be very similar for the nitrate complexes **1a**, **1b** and **1c**. In all three systems there is strong scattering of the data when plotted according to eqn. (4). A closer look at the rate constants k_Y obtained (see Table V) reveals, however, some interesting details, namely: (i) for a given nucleophile Y rate constant k_Y follows the sequence $k_Y(\text{1a}) < k_Y(\text{1b}) < k_Y(\text{1c})$, and, (ii) the relative nucleophilicity of a bulky nucleophile such as Ph₃P seems to increase when the *cis* donor group Net_2 (**1a**) is replaced by NHet (**1b**) and SEt (**1c**).

Table VI presents relative rate constants which indeed prove the trends described above. For relatively small nucleophiles such as Cl^- , Br^- , py and TU the relative ratio of rate constants averages to approximately 63:35:1, which means that the rate of solvent substitution is approximately 35 fold and 63 fold enhanced when the *cis* donor group $D = \text{Net}_2$ in the complex species $[\text{Pt}(\text{OND})(\text{H}_2\text{O})]^+$ is replaced by $D = \text{NHet}$ and $D = \text{SEt}$, respectively. This behavior has to be attributed to steric 'cis-blocking' (i.e., the bulkier $-\text{Net}_2$ donor group blocks more than the NHet donor group) and to the *cis*-effect

Fig. 3. The dependency $\log k_Y = f(n_{Pt}^0)$ for solvent substitution in the cations $[Pt(OND)(H_2O)]^+$ with $D = NEt_2$ (a), $D = NHet$ (b) and $D = SEt$ (c) (the numbering of the nucleophiles Y corresponds to that in Table V).

of the SEt group instead of the NHet group. When it comes to sterically more demanding nucleophiles, however, the effects become more drastic. For the large anion I^- the relative ratio of rate constants amounts to 146:75:1 and for the very bulky ligand Ph_3P an even higher ratio is obtained, namely 2640:192:1. These results are clearly indicative of steric crowding in the transition state following the order:

$NEt_2 > NHet > SEt$ (*cis*-effect of D)

$Ph_3P \gg I^- > Br^-, TU, py, Cl^-$ (effect of entering nucleophile Y)

So, the combination $Y = Ph_3P$ and $D = -NEt_2$ yields for steric reasons a drastically reduced rate of solvent substitution, although Ph_3P is known to be a very strong nucleophile.

Activation Parameters

The temperature dependence of solvent substitution in the complex species $[Pt(ONNEt_2)(H_2O)]^+$ was studied for the nucleophiles TU, DMTU, TMTU, DPTU and Ph_3P . The activation parameters derived from this study are presented in Table VII. The values obtained for the enthalpy of activation range from 48 ($Y = TMTU$) to 62 ($Y = DMTU$) kJ mol^{-1} and do not differ strongly. The spread in $\Delta S^\ddagger$ is greater and the limits of error for this parameter as well. All values obtained for $\Delta S^\ddagger$ are clearly negative, however, thus corroborating the associative character of the substitution reactions studied.

Substituent Effects

It is to be expected that the kinetic effects caused by substituents introduced in the aromatic ring of the Schiff base ligand depend significantly on their posi-

^aStandard conditions: $I = 0.2 \text{ M}$ (NaClO_4), $[\text{complex}] = 10^{-4} \text{ M}$; at each temperature five kinetic runs were carried out to obtain five rate constants k_{obs} at different concentrations of the nucleophile Y in the range $[\text{Y}] = 1 \times 10^{-3} - 5 \times 10^{-2} \text{ M}$. ^bWave-length for observation. ^cAs obtained from the slope of the plot $k_{\text{obs}} = k_Y[\text{Y}]$ according to eqn. (12) by least-squares fitting.

tion relative to the donor atoms O(phenolic oxygen) and N(aldimine nitrogen).

Substituents X^5 are in *para* position to the phenolic oxygen and will decrease or increase the electron density at the donor oxygen and, hence, at the metal. Since the nucleophilic attack of the entering ligand is supposed to occur at the metal, rate constant k_Y should follow the electron releasing or electron withdrawing nature of substituents X^5 . Table VIII summarizes the data obtained and Fig. 4 presents a plot of $\log k_Y$ ($Y = \text{Br}^-$) versus Hammett's substituent constant σ_p , which indeed proves this

Fig. 4. The dependence of rate constant k_Y for solvent substitution in the cation $[\text{Pt}(X^5\text{-ONNEt}_2)(\text{H}_2\text{O})]^+$ by bromide ions on Hammett's substituent constant σ_p .

correlation. Despite some scattering of the data the electron withdrawing substituents $X^5 = \text{NO}_2$, Br, I clearly enhance the rate of solvent substitution by bromide ions and the reaction constant ρ amounts to $+0.71 \pm 0.1^*$. The overall kinetic effect of substituents X^5 is small, however, and even for $X^5 = \text{NO}_2$ the increase in rate is only fivefold for $Y = \text{Br}^-$ and sevenfold for $Y = \text{SCN}^-$ (see Table VIII). In addition, it should be pointed out that the order of nucleophilicity of the entering ligands Y is not substantially changed by substituents X^5 (see Table VIII).

Substituents X^4 are in *meta* position to the phenolic oxygen but could, in principle, act as *para* substituents for the donor nitrogen of the aldimine group, located *trans* to the leaving water molecule. For $X^4 = \text{MeO}$ (with $\sigma_m = +0.12$ and $\sigma_p = -0.27$) and for $Y = \text{Br}^-$ the kinetic substituent effect is, however, very small. As compared to the non-substituted complex ($X^3 = X^4 = X^5 = \text{H}$) the rate is reduced only by 7% (see Table VIII).

The kinetic data obtained for solvent substitution in the complex $[\text{Pt}(\text{ONNEt}_2)(\text{H}_2\text{O})]^+$ carrying substituents X^3 (i.e., in *ortho* position to the phenolic oxygen) are interesting in the sense that they again

*The parameter ρ is obtained from the slope of the solid line (as calculated by least-squares fitting) in Fig. 4.

TABLE VIII. Substituent Effects on Rate Constant k_Y for Solvent Substitution in the Complex Cation $[\text{Pt}(\text{ONNEt}_2)(\text{H}_2\text{O})]^+$ According to Reaction (eqn. (11))^a

Substituents			λ^b (nm)	Nucleophile Y	$k_Y \times 10^2^c$ ($\text{M}^{-1} \text{s}^{-1}$)	$k_Y(\text{rel})^d$
X^3	X^4	X^5				
H	H	Br	330	TU	497 $\pm 2\%$	0.936
H	H	Br	330	Br^-	6.74 $\pm 1\%$	1.61
H	H	Br	320	Ph_3As	5.0 $\pm 1\%$	1.20
H	H	I	330	TU	594 $\pm 1\%$	1.12
H	H	I	410	Ph_3P	36.7 $\pm 2\%$	2.37
H	H	I	330	Br^-	6.23 $\pm 2\%$	1.49
H	H	I	330	Cl^-	3.63 $\pm 1\%$	1.66
H	H	I	320	TCM^-^e	3.18 $\pm 1\%$	1.49
I	H	I	410	Ph_3P	5.82 $\pm 2\%$	0.375
I	H	I	330	Br^-	3.32 $\pm 2\%$	0.794
H	H	NO_2	380	SCN^-	153 $\pm 6\%$	6.89
H	H	NO_2	380	Br^-	20.9 $\pm 1\%$	5.00
H	H	Me	320	Bu_3P	44.7 $\pm 1\%$	0.813
H	H	Me	330	SCN^-	17.5 $\pm 2\%$	0.788
H	H	Me	420	Ph_3P	18.9 $\pm 1\%$	1.22
H	H	Me	330	Br^-	3.75 $\pm 1\%$	0.897
H	H	Me	330	Cl^-	2.09 $\pm 1\%$	0.954
H	H	Me	302	py	0.592 $\pm 1\%$	0.867
H	H	Me	320	TCM^-^e	2.09 $\pm 1\%$	0.98
t-Bu	H	Me	330	SCN^-	17.6 $\pm 1\%$	0.793
t-Bu	H	Me	330	Br^-	2.18 $\pm 1\%$	0.522
t-Bu	H	Me	330	Cl^-	0.903 $\pm 1\%$	0.412
t-Bu	H	Me	325	TCM^-^e	3.76 $\pm 1\%$	1.76
t-Bu	H	Me	410	Ph_3P	0.310 $\pm 1\%$	0.020
H	MeO	H	375	Ph_3P	18.3 $\pm 2\%$	1.18
H	MeO	H	300	Br^-	3.87 $\pm 1\%$	0.926
H	H	MeO	420	Ph_3P	14.6 $\pm 3\%$	0.942
H	H	MeO	330	Br^-	3.98 $\pm 2\%$	0.952

^aStandard conditions: $I = 0.2 \text{ M}$ (NaClO_4), $T = 20^\circ \text{C}$, $[\text{complex}] = 10^{-4} \text{ M}$; for each nucleophile Y five kinetic runs were carried out to obtain five rate constants k_{obs} in the concentration range $[Y] = 1 \times 10^{-3} - 0.1 \text{ M}$. ^bWavelength for observation. ^cAs obtained from the slope of the plot $k_{\text{obs}} = k_Y[Y]$ according to eqn. (12) by least-squares fitting. ^dThe parameter $k_Y(\text{rel})$ is a relative rate constant as obtained by dividing k_Y for the substituted complex by k_Y for the non-substituted complex (with $X^3 = X^4 = X^5 = \text{H}$). ^eThe tricyanomethanide ion TCM^- was introduced as NaTCM , prepared from KTCM [17] by reaction with NaClO_4 .

point to the major role of steric effects. For substituents $X^3 = \text{I}$ and $X^3 = \text{t-Bu}$ and for $Y = \text{Ph}_3\text{P}$ and Br^- , rate constant k_Y is more strongly reduced than expected on the basis of purely electronic effects. The rate of solvent substitution by Ph_3P in $[\text{Pt}(3,5\text{-I}_2\text{-ONNEt}_2)(\text{H}_2\text{O})]^+$ is sixfold slower than in $[\text{Pt}(5\text{-I-ONNEt}_2)(\text{H}_2\text{O})]^+$ and for the couple $[\text{Pt}(3\text{-t-Bu-5-Me-ONNEt}_2)(\text{H}_2\text{O})]^+ / [\text{Pt}(5\text{-Me-ONNEt}_2)(\text{H}_2\text{O})]^+$ the rate reducing factor is even 61 (see Table VIII). It is obvious that these findings demonstrate steric difficulties in the formation of the transition state,

due to the proximity of substituents X^3 to the reaction centre.

Further Studies and Results

Solvent substitution in the complex cation $[\text{Pt}(\text{ONNEt}_2)(\text{H}_2\text{O})]^+$ according to eqn. (11) was not only studied with the thirteen nucleophiles Y listed in Table V, but in addition with a variety of others.

Although it was not possible (see above) to determine the n_{Pt}^0 value for the pseudo-halide ion TCM^- (tricyanomethanide, $\text{C}(\text{CN})_3^-$), reaction (eqn. (14))

could be followed spectrophotometrically under standard conditions and led to $k_Y = 2.13 \times 10^{-2} \pm 0.5\% \text{ M}^{-1} \text{ s}^{-1}$. This rate constant is very close to the one obtained for $Y = \text{Cl}^-$ ($k_Y = 2.19 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$; see Table V) and one can classify, therefore, the TCM^- ion as a poor nucleophile with an estimated n_{Pt}^0 value of 3.03. Much less nucleophilic are the anions NO_3^- and ClO_4^- , for which no changes in the spectrum of the cation $[\text{Pt}(\text{ONNet}_2)(\text{H}_2\text{O})]^+$ could be observed, even in the presence of a large excess of these anions.

The nucleophiles $Y = \text{AcO}^-$, OH^- , piperidine and 2,6-lutidine represent an interesting group of ligands in the sense that their reaction with the complex $[\text{Pt}(\text{ONNet}_2)(\text{H}_2\text{O})]^+$ is too fast to be measured by stopped-flow techniques ($k > 100 \text{ s}^{-1}$). What one observes with these nucleophiles is a very fast jump in the spectrum, obviously associated with the deprotonation of the complex according to eqn. (15):

The hydroxo complex formed appears to be kinetically inert, i.e., there is no further reaction to be observed. The formation of bridged dinuclear platinum species cannot be excluded under these conditions.

While a strong base such as the OH^- ion obviously deprotonates the coordinated water completely, there is another group of ligands Y (namely, $Y = \text{DCA}^-$, py, NO_2^- , imidazol, N_3^- , CN^- , N -methylimidazol and HCOO^-) which only partially deprotonate the aquo complex $[\text{Pt}(\text{ONNet}_2)(\text{H}_2\text{O})]^+$ according to eqn. (15). The experimental observation with these less basic nucleophiles is a small, but fast jump in the spectrum (too fast for stopped-flow monitoring), followed by a slower, observable reaction. In the case of the anion DCA^- (= dicyanoamide ion) the slower reaction leads to $k_Y = 1.6 \times 10^{-2} \pm 3\% \text{ M}^{-1} \text{ s}^{-1}$ under standard conditions. This k_Y value is in line with $k_Y = 2.19 \times 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ for $Y = \text{Cl}^-$ and the fact that the corresponding n_{Pt}^0 values are very similar ($n_{\text{Pt}}^0(\text{DCA}^-) = 3.05$; $n_{\text{Pt}}^0(\text{Cl}^-) = 3.04$).

It should be pointed out that the k_Y value presented in Table V for $Y = \text{py}$ was obtained in the presence of a buffer system to avoid partial deprotonation of the aquo complex according to eqn. (15).

Conclusions

The concept of nucleophilic discrimination as based on eqn. (4) correlates the second-order rate constant k_Y for bimolecular ligand substitution in 4-coordinate Pt(II) complexes with the n_{Pt}^0 scale as derived for the standard substrate $\text{trans}[\text{Pt}(\text{py})_2\text{Cl}_2]$.

Although for certain nucleophiles Y (such as thiourea, SeCN^- , NO_2^- , SCN^-), and certain platinum complexes (differing in charge, e.g.) deviations from eqn. (4) were [1] and are [19] reported, the relationship (eqn. (4)) was successfully applied to several Pt(II) complexes other than $\text{trans}[\text{Pt}(\text{py})_2\text{Cl}_2]$ [1]. The attempt to apply eqn. (4) to solvent substitution in Pt(II) complexes of the type **1a–1c** according to $[\text{Pt}(\text{OND})(\text{H}_2\text{O})]^+ + Y \rightarrow [\text{Pt}(\text{OND})Y]^+ + \text{H}_2\text{O}$ fails in the sense that the k_Y data obtained for a series of nucleophiles Y cannot be fitted to eqn. (4) adequately, even after correction for electrostatic effects. It follows from the present study that steric effects hindering the formation of the 5-coordinate transition state are obviously controlling the deviations observed. The type of steric hindrance occurring has to be classified as a steric *cis* effect which arises for rather bulky attacking nucleophiles Y (such as Ph_3P , Bu_3P , Ph_3As) from sterically demanding *cis* donor groups D (such as $D = \text{NEt}_2$ and, to a lesser extent, $D = \text{NHet}$, SEt). The rate-reducing effect of the *cis* donor group D is of the order $k_Y(D = \text{SEt}) : k_Y(D = \text{NHet}) : k_Y(D = \text{NEt}_2) = 63:35:1$ for small nucleophiles Y and as large as 2640:192:1 for $Y = \text{Ph}_3\text{P}$. Additional steric crowding is created by bulky substituents X^3 (= *t*-Bu, I) neighboring the phenolic oxygen, which is coordinated in *cis* position to the leaving ligand. The kinetic effects of substituents X^4 and X^5 in *meta* and *para* position to the phenolic oxygen are rather small.

The hitherto unknown nucleophilicity of the pseudo-halide ions DCA^- (= $\text{N}(\text{CN})_2^-$) and TCM^- (= $\text{C}(\text{CN})_3^-$) proves to be low and close to that of the Cl^- ion.
