ABSTRACT

The reaction of benzyloxyfluorodiazirine (**3**) with SbF₅ in benzene gives PhCH₂OCF, which undergoes SbF₅-mediated fragmentation to PhCH₂⁺, CO, and SbF₆[−]; the benzyl cation alkylates benzene to yield diphenylmethane. Phenoxyfluorodiazirine (**4**) reacts with SbF₅ in benzene to give PhOCF and (ultimately) triphenylmethane by a pathway that avoids fragmentation.

We recently reported that the reaction of, for example, benzyloxychlorodiazirine (**1**) with AlCl₃ in benzene preferentially proceeds by Lewis acid attack at the diazirine N electron pair, rather than at Cl.² The sequelae include, AlCl₃-mediated nitrogen loss affording benzyloxychlorocarbene (PhCH₂OCCl), fragmentation of the carbene to benzyl cation, and alkylation of solvent benzene by PhCH₂⁺ yielding diphenylmethane. No evidence could be found for competitive chloride abstraction by AlCl₃ to generate the benzyloxydiazirinium cation (**2**).² Evidence for diazirinium cations

remains stubbornly absent,³ despite their potential involvement in the Graham oxidation of amidines to halodiazirines.⁴

In a renewed attempt to generate diazirinium ions, we have now subjected the reactions of benzyloxyfluorodiazirine (**3**) and phenoxyfluorodiazirine (**4**) with SbF₅ to experimental and computational scrutiny. These substrates were selected to parallel previously studied oxachlorodiazirines.² Perhaps the fluorophilic SbF₅ might favor *F*-attack over *N*-attack with oxafluorodiazirines **3** and **4**. In the event, we encountered an unanticipated SbF₅-mediated fragmentation of benzyloxyfluorocarbene.

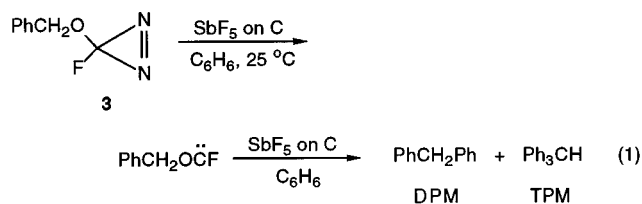

Diazirines **3** and **4** were prepared by fluoride exchange reactions⁵ of the corresponding chlorodiazirines;⁴ experimental details have been published.^{4b,5–7} Diazirine **3** was stirred with a ~20-fold excess of SbF₅ (50 wt % on graphite) in the dark at 25 °C for 1 h, whereupon the SbF₅/C was removed by filtration and UV spectroscopy revealed that **3** (355 nm) was gone. Capillary GC analysis and GC-MS indicated the presence of 77% of diphenylmethane (DPM) and 10% of triphenylmethane (TPM), eq 1.⁸ The absolute yield of DPM, relative to an internal dodecane standard, was 36%.

The principal reaction of **3** with SbF_5 thus parallels the reaction of **1** with AlCl_3 and can be formulated analogously: **3** is converted to benzyloxyfluorocarbene ($\text{PhCH}_2\text{O}\ddot{\text{C}}\text{F}$) by SbF_5 (see below), the carbene largely fragments to benzyl cation, CO , and fluoride, and the cation then alkylates solvent benzene, affording DPM. (Controls demonstrate that benzyl fluoride formed by the fragmentation would undergo SbF_5 -catalyzed Friedel–Crafts reaction with the solvent.) We will return to the TPM-forming pathway of eq 1 below.

The fragmentation of $\text{PhCH}_2\text{O}\ddot{\text{C}}\text{F}$ in eq 1 is striking and unexpected; in the absence of SbF_5 , the carbene resists fragmentation. Thus, the computed activation energy (vacuum) for the fragmentation of $\text{PhCH}_2\text{O}\ddot{\text{C}}\text{F}$ is 27 kcal/mol, compared to only 6.7 kcal/mol for PhCH_2OCCl .⁹ Indeed,

thermolysis at 80°C or photolysis of **3** in MeCN is reported to give less than 10% of PhCH_2F by fragmentation. Benzyl difluoromethyl ether ($\text{PhCH}_2\text{OCHF}_2$) and benzyl formate are the major reaction products, resulting from HF or water capture of PhCH_2OCF , respectively.⁷

Repetitions of these experiments in benzene also afforded scant carbene fragmentation, although the product mixtures were complex. Thermolysis of **3** in benzene at 100°C in the dark gave (inter alia) 5.3% of PhCH_2F , 27% of benzaldehyde, 24% of $\text{PhCH}_2\text{OCHF}_2$, and 16% of benzyl formate. Photolysis of **3** in benzene gave 1.3% of PhCH_2F , 5% of $\text{PhCH}_2\text{OCHF}_2$, 5% of benzaldehyde, 2.4% of benzyl formate, 1.7% of DPM, 34% of carbene (PhCH_2OCF) dimers, and 39% of bibenzyl. The latter, apparently formed by an unknown radical process, is totally absent in the SbF_5 -catalyzed decomposition of **3**, eq 1. Benzaldehyde (origin unknown) is also absent in the SbF_5 -induced reaction. Clearly, the relatively clean formation of DPM here must be the result of SbF_5 mediation.

Phenoxyfluorocarbene (PhOCF) is also resistant to fragmentation: the computed $E_a(\text{vacuum}) = 41.8 \text{ kcal/mol}$,⁹ and,

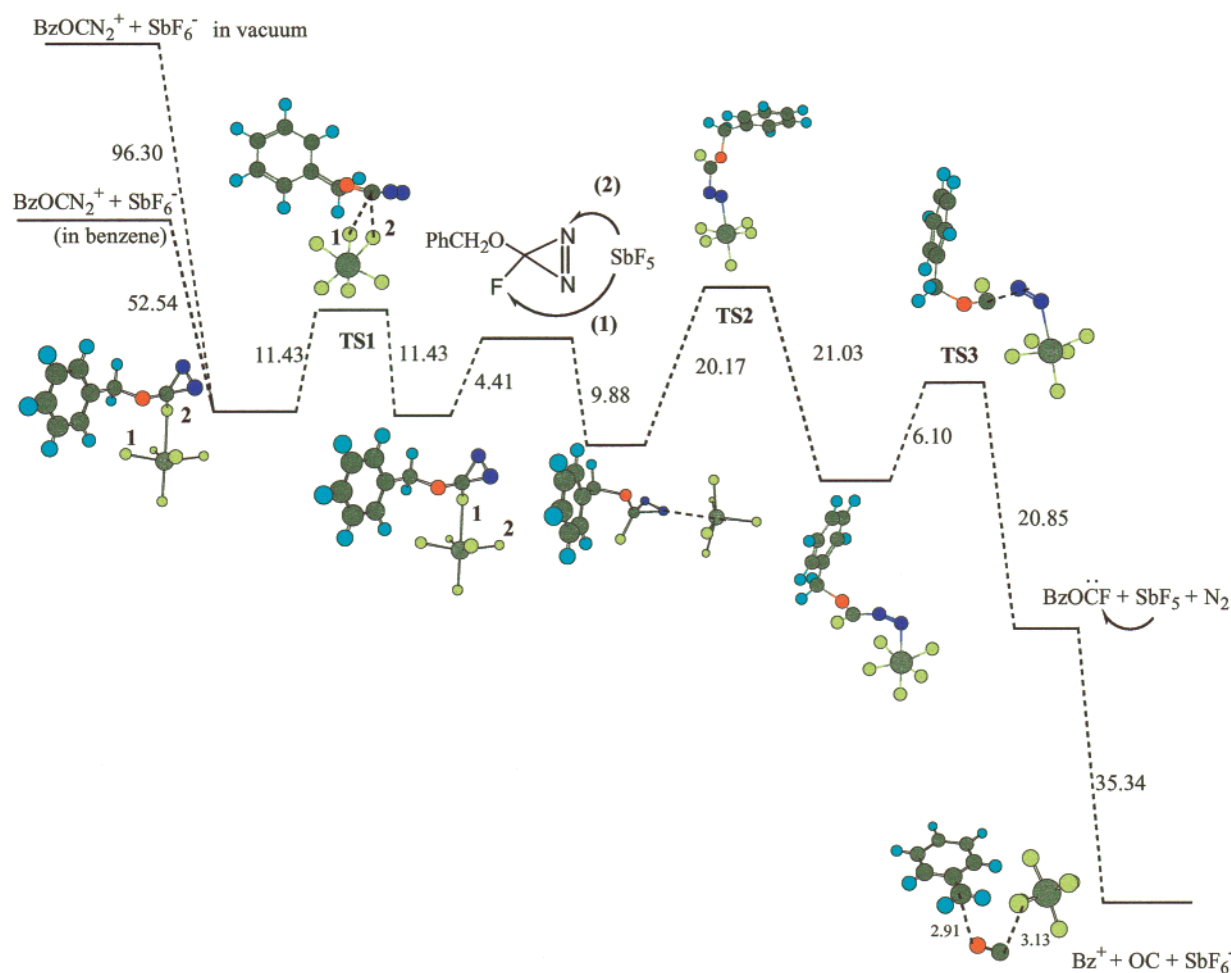

Figure 1. B3LYP/6-31G* reaction profile for the SbF_5 -mediated conversion of diazine **3** to the benzyl cation. Calculations are for the gas phase with zero point energy and thermal corrections.¹¹ Arabic numerals refer to energies (kcal/mol), unless they appear next to (dashed) bonds, where they represent separations (Å).

experimentally, the intact carbene can be readily captured by various alkenes.⁶ When diazirine **4** is stirred with excess SbF₅/C in benzene (32 °C, dark, 6 h), TPM is formed in >95% purity.¹⁰ In contrast, the photolysis of **4** in benzene gave mainly the HF trapping product, PhOCHF₂, and dimers of PhOCF. TPM formation from the reaction of **4** with SbF₅ in benzene is analogous to the reaction of phenoxychlorodiazirine with AlCl₃ in benzene, which also gives TPM.² The origin of this product is discussed below.

Computational studies were performed to evaluate mechanistic possibilities for the reactions of **3** with SbF₅. B3LYP/6-31G* techniques afforded the results summarized in Figure 1.¹¹ We readily located two complexes formed by SbF₅ bonding to diazirine **3** at either fluorine (1) or nitrogen (2); these complexations were exothermic by 4.4 or 9.9 kcal/mol, respectively.

The *F*-complex undergoes a facile “*F*-interchange” reaction over a barrier (TS 1) of 11.4 kcal/mol; details of the *F*-complex and TS 1 appear in Figure 2. The *F*-interchange

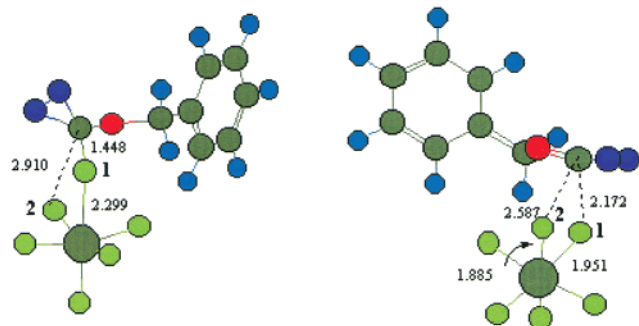

Figure 2. Details of the computed SbF₅–diazirine **3** *F*-complex (left) and TS 1 for the *F*-interchange reaction (right).¹¹ Bond lengths and separations are in Å.

reaction, however, appears to be a cul-de-sac for the *F*-complex. Ionization to diazirinium ion **2** and SbF₆[−] would require 96 kcal/mol in a vacuum or 52.5 kcal/mol in benzene (PCM calculation) and is prohibitively endothermic (although the cost of ionization is reduced to 12.7 kcal/mol in MeCN). Nor could we locate a transition state for the simultaneous rupture of the *F*-complex into the benzyl cation, CO, N₂, and SbF₆[−], which would be exothermic by ~26 kcal/mol in benzene.

The *N*-complex of diazirine **3** and SbF₅, in contrast, does lead to products; cf., Figure 1. In analogy to the AlCl₃-mediated reactions of chlorodiazirines,² the *N*-SbF₅ complex

opens to a SbF₅ complex of *linear* benzyloxyfluorodiazomethane, traversing TS 2 and a barrier of ~20 kcal/mol (net *E*_a = 10.3 kcal/mol from **3**).¹² The diazo complex next loses N₂ via TS 3 (*E*_a = 6.1 kcal/mol), affording PhCH₂OCF with a net exothermicity of 14.7 kcal/mol. The overall effect of the SbF₅, therefore, is to catalyze the loss of nitrogen from **3**, generating benzyloxyfluorocarbene.

Although PhCH₂OCF resists fragmentation when generated photochemically or thermally (see above and ref 7), SbF₅ mediates this process. Computational studies¹¹ indicate that the binding of SbF₅ at the carbene's F atom initiates fragmentation to PhCH₂⁺, CO, and SbF₆[−] with *no* barrier. Figure 3 depicts the carbene and an early stage in the

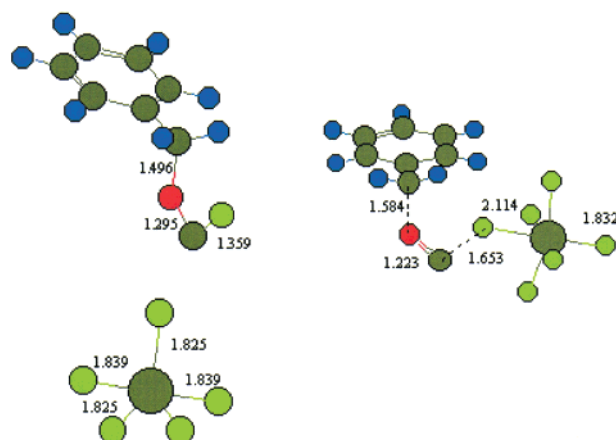

Figure 3. Computed structures¹¹ for benzyloxyfluorocarbene and SbF₅ (left) and for an early stage during the fragmentation of the PhCH₂OCF–SbF₅ complex (right); bond lengths and separations are in Å.

fragmentation of the PhCH₂OCF–SbF₅ assembly. Finally, the benzyl cation generated by the fragmentation alkylates the benzene solvent to give DPM.

TPM is the sole product of the reaction of diazirine **4** and SbF₅ in benzene, and a small quantity of TPM accompanies DPM formation from diazirine **3** and SbF₅. The TPM production can be rationalized by the mechanism outlined in Scheme 1, which resembles one offered for the analogous reaction of phenoxychlorodiazirine and AlCl₃ in benzene.²

Thus, SbF₅ first converts diazirine **4** to PhOCF in the same way that it generates PhCH₂OCF from diazirine **3** (cf., Figure 1). Next, PhOCF (which resists fragmentation^{6,7,9}) reacts with SbF₅ at the carbene carbon to give the antimony-substituted carbocation **5**,¹³ which alkylates benzene via intermediate **6**. Continuations from **6** include (a) loss of HF affording the phenoxyphenylpentafluoroantimony carbocation **7**, which alkylates benzene to give Ph₂(PhO)CH (**10**),¹⁴ (b) loss of HSbF₆ to give phenoxyphenylcarbene (**8**), which is captured

(8) DPM and TPM were verified by GC-spiking experiments with authentic samples. Two unidentified components (5% and 8% of the total GC integrals) were also present.

(12) The gas phase activation energies cited here would likely be lower in benzene solution. Although we did not locate a transition state for the thermal decomposition of **3** to PhCH₂OCF and N₂, this conversion is computed to be endothermic by 22.96 kcal/mol in a vacuum (B3LYP/6-31G*). The SbF₅-mediated process is at least 12.7 kcal/mol less endothermic.

Scheme 1

by SbF_5 to give cation **7** and thence **10**, and (c) loss of SbF_5 , coupled with a proton shift to yield phenoxyphenylfluoromethane (**9**), from which a SbF_5 -catalyzed Friedel–Crafts reaction with benzene would also lead to **10**. Finally, SbF_5 attack on an oxygen lone pair of **10** would initiate another Friedel–Crafts reaction (with phenoxide as the leaving group) in which benzene is alkylated to TPM.

The mechanism of Scheme 1 not only accounts for TPM formation from **4** and SbF_5 in benzene but it also rationalizes

(13) Attack of SbF_5 at the carbenic center of PhOCF is computed to afford **5** with an exothermicity of 34.1 kcal/mol in benzene. The alternative attack at F affords a PhOCF-SbF_5 complex with an exothermicity of 9.0 kcal/mol. However, this complex requires an activation energy of 13.3 kcal/mol for fragmentation (to Ph^+), so that it presumably reverts to $\text{PhOCF} + \text{SbF}_5$ and then to **5**.

(14) Greater detail, including an intermediate analogous to **6**, could be drawn for this step; only an abbreviated rendering appears in Scheme 1.

the TPM side product formed in the analogous reaction of diazirine **3**. Thus, although PhCH_2OCF mainly reacts with SbF_5 at F, initiating carbene fragmentation (77%), competitive trapping at carbenic C would lead to **5** (PhCH_2O in place of PhO), initializing a cascade of reactions analogous to those in Scheme 1 and terminating in TPM (10%).

In summary, the reaction of SbF_5 with benzyloxyfluorodiazirine (**3**) in benzene yields PhCH_2OCF , which affords benzyl cation from a subsequent SbF_5 -mediated fragmentation; the benzyl cation then alkylates benzene, giving diphenylmethane. Phenoxyfluorodiazirine and SbF_5 in benzene react to produce PhOCF . This carbene resists fragmentation, even in the presence of SbF_5 , but reacts with the latter at its carbenic center, affording an antimony-substituted carbocation which starts a chain of benzene alkylation reactions that terminates in triphenylmethane. However, the novel chemistry described here does not include evidence for the intermediacy of diazirinium cations.
