New Octahedral, Asymmetric Iron Carbonyl Complexes

By Marek Pankowski, Wladyslaw Chodkiewicz, Marie-Paule Simonnin, and Marie-José Pouet (L.A. 161 C.N.R.S., Ecole Nationale Supérieure de Chimie, 11, rue P. et M. Curie, 75231 Paris Cedex 05, France)

Summary Isomerization of the prochiral octahedral complex [FeMe(CO)₂(PMe₃)₂(PMe₂Ph)]⁺[BPh₄]⁻(CO-CO cis, PMe₃-PMe₃ trans) leads exclusively to a new chiral molecule by permutation of PMe₂Ph with one of the PMe₃ ligands.

There is considerable interest in the reactivity of asymmetric transition-metal complexes and their role as stereo-

specific catalysts is well recognized.¹ However, recent work in this field deals almost exclusively with tetrahedral systems. The only asymmetric octahedral complexes recently reported²,³ bear chelating ligands. We report here the first synthesis of an asymmetric, octahedral iron complex with monodentate ligands.

Treatment of $FeIMe(CO)_2(PMe_3)_2$ (1)4 in MeOH at -30 °C with PMe_2Ph in the presence of $NaBPh_4$ yields, quantita-

Scheme. Reagents: i, L + NaBPh₄; ii, CD_2Cl_2 solvent; iii, T >— 30 °C.

From the i.r. and low-temperature ¹H n.m.r. spectra structure (2) was assigned to this complex. The observation of two i.r. active bands of equal intensity in the carbonyl region (Table) indicates that the two CO ligands are in mutually cis-positions, as previously found for the complex (1).4 ¹H N.m.r. spectra (CD₂Cl₂, -30 °C) show that the two PMe₃ ligands are isochronous, as their resonance gives a 'filled-in' doublet $(A_n X X' A_n' \text{ spectrum})$, indicating their mutually trans-positions. The structure (2) is confirmed by the presence of a low-field doublet for the methyl groups of the equatorial dimethylphenylphosphine ligand and a highfield doublet of triplets for the methyl group bonded to iron.

³¹P Chemical-shifts determined by double resonance ¹H{³¹P} experiments indicate that, as expected, the two equivalent 31P signals of the axial PMe3 groups are more shielded than the ³¹P signal of the equatorial PMe₂Ph ligand.

A slow isomerization of complex (2) occurs in solution above -30 °C leading to the complex (3) (Scheme), whose formation is almost complete within 1 h at +32 °C. I.r. data of compound (3) indicate that, as previously found for the complex (2), the two CO ligands remain in mutually cispositions.

The isomerization of complex $(2) \rightarrow (3)$ can be followed by the changing ¹H n.m.r. spectra (Figure). They show a progressive disappearance of the 'filled-in' doublet and the concomitant appearance of two distinct doublets of equal intensity, due to the resonance of two anisochronous PMe₃ groups. Furthermore, the methyl groups of the PMe₂Ph ligand give rise to two distinct doublets of equal intensity. This result indicates that the two diastereotopic methyl

groups of the PMe2Ph ligand become non-equivalent in the structure (3).

The assignment of the different signals of complex (3) is confirmed by ³¹P noise irradiation, as each multiplet collapses to a singlet. Selective 31P irradiation experiments show the presence of three different ³¹P nuclei in (3). Therefore, spectral data emphasize the absence of any elements of symmetry in the molecule (3), where the metal centre is chiral.

Some complexes similar to complex (2) which are substituted by other equatorial phosphorus ligands such as P(OMe)₂Ph or PEtPh₂ have been examined. No isomerization is observed in the first case while a total switch occurs in the second. These preliminary results indicate that steric strain is the essential driving force which induces permutation of a bulky equatorial ligand with one of the PMe₃ axial ligands. The final, chiral molecule has a lower steric interaction.
