Abstract: The H₂N₃+ salts of SbF₆-, AsF₆-, and BF₄- have been prepared and, for the first time, been isolated from HF solutions of HN₃ and the corresponding Lewis acids. They are hygroscopic white solids which are stable at room temperature. The crystal structure of H₂N₃+SbF₆ was determined at 20 K. This compound crystallizes in the orthorhombic system, space group $Pmc2_1$, with two molecules in a unit cell of dimensions a = 5.794 (3) Å, b = 5.113 (2) Å, and c = 9.919 (5) Å with R = 0.015, $R_{\rm w} = 0.022$, for 587 observed $[I > 3\sigma(I)]$ reflections. In addition to two almost perfectly octahedral SbF₆ anions, the unit cell contains two asymmetric $H_2N_3^+$ cations with N(1)-N(2)=1.295 (5) Å, N(2)-N(3)=1.101 (6) Å, and N(1)-N(2)-N(3)=1.101= 175.3 (5)° and both hydrogens bonded to the same nitrogen atom, N(1). The infrared and Raman spectra of these salts were also recorded. Local density functional calculations were carried out for H₂N₃⁺ and isoelectronic H₂NCN and used for the assignment of the observed vibrational spectra and the determination of their force fields. The general agreement between the calculated and observed geometries and frequencies is very good. The results from the LDF calculations indicate that the H_2N group in H_2N_3 is less pyramidal than that in H_2NCN and, therefore, possesses a lower inversion energy barrier.

Introduction

During our attempted fluorination of HN₃ in anhydrous HF solutions using either XeF+AsF₆ or F₂ and the Lewis acids SbF₅, AsF₅, and BF₃, stable white solids were isolated which were identified as H₂N₃⁺ salts of the corresponding Lewis acids. Relatively little had been known about salts derived from protonated hydrazoic acid. In 1966, Schmidt reported⁵ the preparation of H₂N₃+SbCl₆- from the reaction of HN₃ with SbCl₅ and HCl in CH₂Cl₂ at -78 °C. On the basis of the observation of an infrared band at 1522 cm⁻¹, which on deuteration was shifted to 1163 cm⁻¹, he proposed that $H_2N_3^+$ has the asymmetric aminodiazonium structure, $H_2N-N_2^+$, and not the symmetric diazenium structure, $[HN-N-N]^+$. However, out of the nine fundamental vibrations expected for H₂N-N₂⁺, only four were experimentally observed, and no explanation was offered for the absence of the other five bands. In 1983, Olah and co-workers studied the protonation of HN₃ in HF/SbF₅, HF/BF₃, and HSO₃F/SbF₅ solutions.⁶ By ¹H and ¹⁵N NMR spectroscopy, they unequivocally established that H₂N₃+ has indeed the asymmetric aminodiazonium structure but did not isolate or further characterize these salts. On the basis of ab initio molecular orbital calculations at the 3-21G level of theory, they furthermore concluded that the aminodiazonium structure, H₂N-N₂⁺, is favored by 49.8 kcal mol⁻¹ over the symmetric diazenium structure, [HN=N=NH]⁺ and that the optimized $H_2N-N_2^+$ structure has the following planar configuration of symmetry C_{2v} :

$$H = N(1) - N(2) - N(3)$$

To our knowledge, no other studies on aminodiazonium salts have been published.

Experimental Section

Caution! Neat hydrazoic acid is shock sensitive, and proper safety precautions, such as working on a small scale and using safety shields, should be taken when handling the material.

Materials. HN3 was prepared from NaN3 and stearic acid at 110-130 °C.7 HF (Matheson) was dried by storage over BiF_{5.8} AsF₅, SbF₅ (Ozark Mahoning), and BF3 (Matheson) were purified by fractional condensation prior to use.

Apparatus. HN₃ was generated and handled on a Pyrex vacuum line equipped with Kontes Teflon valves. HF and the Lewis acids were handled in a stainless steel-Teflon-FEP vacuum system, 9 and solids, in the dry N₂ atmosphere of a glovebox. Vibrational spectra were recorded as previously described.10

Preparation of H₂N₃+AsF₆. A prepassivated (with ClF₃ and HF) Teflon-FEP ampule that was closed by a stainless steel valve was loaded on the metal vacuum line with HF (4.6 g). On the Pyrex line, HN₃ (2.73 mmol) was added at -196 °C, and the mixture was homogenized at room temperature. AsF₅ (2.86 mmol) was added on the metal line at -196 °C. and the mixture was warmed to -78 °C for 1.5 h. The HF solvent and the unreacted starting material were pumped off while the ampule was warmed slowly to ambient temperature. Pumping was continued for 1 h at 20 °C. The ampule contained 633 mg of a white solid (weight calculated for 2.73 mmol of $H_2N_3^+AsF_6^-$ = 636 mg) which was identified by vibrational spectroscopy and X-ray diffraction as H₂N₃+AsF₆.

Preparation of H₂N₃+SbF₆. Antimony pentafluoride (2.74 mmol) was transferred on the metal line in a dynamic vacuum into a prepassivated Teflon-FEP U-tube that was kept at -78 °C and closed by two stainless steel valves. Anhydrous HF (1.6 g) was added at -196 °C, and the mixture was briefly warmed to room temperature. Hydrazoic acid (3.23 mmol) was added at -196 °C on the Pyrex line, and the mixture was warmed to room temperature. All material, volatile at room temperature, was pumped off for 30 min, resulting in a white, stable solid (760 mg; weight calculated for 2.74 mmol of H₂N₃+SbF₆⁻ = 766 mg) which was identified by vibrational spectroscopy and a crystal structure determination as H2N3+SbF6

Preparation of H₂N₃+BF₄. According to the procedure described above for H₂N₃+AsF₆, HN₃ (2.88 mmol) was combined with BF₃ (3.23 mmol) in HF (5.66 g). Warming of the resulting mixture from -196 to -78 °C produced a gel-type product which on further warming to -22 °C formed a clear solution. Volatile products were pumped off at -22 °C for 2 h and at 20 °C for 10 min, leaving behind 379 mg of a white, somewhat tacky, solid (weight calculated for 2.88 mmol of H2N3+BF4-= 377 mg) which was identified by vibrational spectroscopy as $H_2N_3^+$

Crystal Structure Determination of H₂N₃+SbF₆. Single crystals of H₂N₃+SbF₆ were obtained by recrystallization from anhydrous HF solution. Suitable crystals were selected under a microscope inside the glovebox and sealed in quartz capillaries. Initial data collection was carried out at room temperature on a Siemens P21 diffractometer. The structure was solved and refined to an agreement factor of R = 0.049 for 409 reflections. This structure revealed an asymmetric H₂N₃⁺ cation with two poorly-defined H atoms attached to one of the terminal N atoms. Since the hydrogen positions in this room-temperature X-ray analysis were not entirely satisfactory, it was decided to re-collect data at low temperature.

Low-temperature diffraction data were collected on a four-circle Huber diffractometer equipped with a closed-cycle helium refrigerator.¹¹ The crystal was slowly cooled, over a period of 4 h, to 20 (5) K. Accurate unit cell parameters at this temperature were obtained by least-squares refinement of 15 centered reflections and are listed in Table I together with other details of data collection and structure refinement. Intensity data at 20 K were collected with the θ -2 θ step scan technique, up to a maximum 2θ of 65°. Three standard reflections measured after every 97 reflections showed no decay. A total of 2095 reflections were measured over one hemisphere of reciprocal space and were then averaged for multiple observations to give a set of 649 unique reflections. R(av)was 0.024. Corrections for Lorentz and polarization effects were made, and an empirical absorption correction was applied using the ψ -scan procedure.

The position of antimony was determined from a Patterson map, and the remaining non-hydrogen atom positions were obtained from the initial difference Fourier map. The structure was then refined using 587 reflections with $I > 3\sigma(I)$, first with isotropic and later with anisotropic thermal parameters. At this point, a difference electron density map revealed the positions of the hydrogen atoms at a distance of 0.85 Å from N(1). In the final cycles of least-squares refinement, the hydrogen atom positions were also refined with a fixed isotropic temperature factor. The assigned thermal parameter for the hydrogen atoms was 30% higher than the average isotropic thermal parameters of the rest of the atoms, excluding Sb. Refinement converged with final agreement factors of R(F)= 0.015 and $R_w(F)$ = 0.022 and GOF = 1.024. In the final difference map, except for two ripples associated with Sb (1.55 and 1.51 e/Å³ about 0.68 and 0.75 Å away, respectively), the maximum residual electron

Final atomic coordinates with equivalent isotropic thermal parameters are listed in Table II. Interatomic distances and angles are given in Table III, and the anisotropic temperature factors are listed in Table 1S in the supplementary material. An Ortep plot of the molecule is shown in Figure 1, and unit cell packings along the b and a axes are shown in Figures 2 and 3, respectively.

Crystal Structure Determination of H₂N₃+AsF₆. This compound crystallizes in the orthorhombic space group Pma2 (No. 28), with a =20.056 Å, b = 5.468 Å, c = 5.523 Å, V = 604.7 Å³, and Z = 4. Data were collected at room temperature, and the structure was refined to an agreement factor of R = 0.057 for 387 nonzero reflections. The structure shows a linear and apparently almost symmetric $H_2N_3^+$ cation [N-N=1.16 (2) and 1.19 (2) $^{\text{A}}$; N-N-N = 177 (2)°]. However, the structure analysis was marred by extensive disordering of the AsF₆ anion, and it is quite possible that the H₂N₃⁺ cation suffers from a 2-fold packing disorder as well. The H atoms in H₂N₃+AsF₆ could not be located.

Computational Methods. The geometry, vibrational frequencies, and force field of H₂N₃⁺ were calculated, as previously described, 13 in the local density functional (LDF) approximation by using the program system DMol with a polarized double numerical basis set.

Results and Discussion

Syntheses and Properties of H₂N₃⁺ Salts. Protonation of HN₃ by mixtures of HF and the strong Lewis acids SbF₅, AsF₅, and BF₃, followed by removal of solvent and unreacted starting ma-

Scattering factors and for X-ray Crystallography; Kynoch Press; Birmingham, England, 1974; Vol. 1V. All calculations were performed on a DEC VAX 3100 cluster.

(13) (a) Christe, K. O.; Wilson, R. D.; Wilson, W. W.; Bau, R.; Sukumar, S.; Dixon, D. A. J. Am. Chem. Soc. 1991, 113, 3795. (b) Dixon, D. A.; terial at room temperature, produces the H₂N₃⁺ salts of SbF₆⁻, AsF_6^- , and BF_4^- , respectively.

$$HN_3 + HF + XF_n \xrightarrow{HF} H_2N_3^+XF_{n+1}^-$$

Although the existence of the H₂N₃⁺ cation in these solutions had previously been established by multinuclear NMR spectroscopy,6 the actual salts had not been isolated and characterized. All salts are white, crystallinic solids that are stable at room temperature. They are strongly hygroscopic and, when exposed to moisture, form the corresponding H₃O⁺ salts¹⁴

$$H_2N_3^+SbF_6^- + H_2O \rightarrow H_3O^+SbF_6^- + HN_3$$

as expected from H₂O being a stronger base than HN₃ and, therefore, being able to displace HN₃ from its salts.

X-ray Crystal Structure of H₂N₃+SbF₆. The crystal structure of H₂N₃+SbF₆ was determined both at room temperature and at 20 K. The structures were almost identical at both temperatures (see Table III and footnote), but the low-temperature data were of much better quality. The structure consists of well-separated H₂N₃⁺ and SbF₆⁻ ions (see Figure 1). The SbF₆⁻ anion is a nearly perfect octahedron with angles ranging from 89.15 (9) to 90.5 (1)° and identical Sb-F bond lengths of 1.885 (3) Å. The H₂N₃⁺ cation is asymmetric, with both hydrogens attached to the same nitrogen. Furthermore, the two N-N bond distances are very different, the N-N-N group is slightly distorted from linearity $(N(1)-N(2)-N(3) = 175.3^{\circ})$, and the NH₂ group is pyramidal. These findings demonstrate that the structure of $H_2N_3^+$ is best described by I, with little contribution from resonance structure

II. The fact that the repulsion from the free valence electron pair on N(1) is larger than those from the two hydrogen ligands can account for N(2) being slightly bent away from this free pair. The observed N-N bond lengths are in good agreement with our expectations for an N-N single and an N≡N triple bond, and their differences are more pronounced than those found for other covalent azides such as CF_3N_3 (N(1)-N(2) = 1.252 (5) Å, N-(2)-N(3) = 1.118 (3) Å)¹⁵ or FN_3 (N(1)-N(2) = 1.253 (10) Å, N(2)-N(3) = 1.132 (10) Å).¹⁶ The observed N-H bond length of 0.76 (7) Å is unrealistically short due to the fact that hydrogen does not possess any core electrons, and therefore, the X-rays are being diffracted by the binding electrons. This results in an artificially short N-H bond length, which is no surprise in view of the well-known difficulties of obtaining reliable hydrogen bond lengths by X-ray diffraction. On the basis of the ab initio calculation (see below), a realistic N-H bond distance in H₂N₃⁺ is about 1.01 Å. The H-N-H and H-N-N bond angles, on the other hand, should not be affected, as the binding electrons are located along the N-H bond axes, and, therefore, are considered more reliable.

A packing diagram of H₂N₃+SbF₆ is shown in Figure 2. The anion and the cation are located on crystallographic mirror planes. The anionic mirror plane passes through the atoms F(3)-Sb-F(4) whereas the cationic mirror plane passes through all three nitrogen atoms and bisects the H-N-H angle. The cations are stacked parallel to each other down the crystallographic b axis (see Figure 2) but are oriented perpendicular to each other in the b-c plane, causing a doubling of the repeat distance along the c axis. The nearest anion-cation interactions are N(1)...F(1) at 2.765 Å and H(1)...F(1) at 2.127 Å, which are significantly shorter than the

sums of their Pauling van der Waals radii.¹⁷ Although these short distances suggest appreciable hydrogen-fluorine bridging, they do not result in a significant distortion of the SbF₆⁻ octahedron (see above).

The above crystal structure demonstrates that H₂N₃⁺ has indeed the asymmetric aminodiazonium structure. This is not surprising in view of a previous ab initio calculation which indicated that the aminodiazonium structure is 49.8 kcal mol⁻¹ more favorable than the symmetric diazenium structure.⁶ It must be pointed out, however, that, in spite of the good agreement between the predicted⁶ and our observed N-N bond lengths (1.305 and 1.088 Å versus 1.295 (5) and 1.101 (6) Å), the previous calculation⁶ predicted a planar NH₂ group whereas the crystal structure and our LDF calculations (see below) show that the NH₂ group in H₂N₃⁺ is pyramidal. This was due to the lack of polarization functions on the nitrogens at the 3-21G level.

Computational Results. To support our analysis of the vibrational spectra of the H₂N₃⁺ cation, the structure, vibrational frequencies, and force field of the free H₂N₃⁺ cation in the gas phase were calculated using local density functional (LDF) theory. To test the quality of these computations, the electronic structure of the known, 18-32 isoelectronic cyanamide molecule, H2NCN, was

the experimental frequency values better than calculations at either the 4-31G*24 or 6-31G*22 level. In agreement with previous calculations at the 4-31G²⁴ or higher levels²² for H₂NCN, the lowest energy structure found for H₂N₃⁺ by using LDF theory is nonplanar (C_s symmetry) with a pyramidal amino group. The planar C_{2n} structure previously calculated for $H_2N_3^+$ at the 3-21G level⁶ is due to the lower level of theory used and, for isoelectronic H2NCN, represents a saddle point on the potential energy surface.²² It should also be pointed out that LDF theory predicts the H_2N-N group in $H_2N_3^+$ to be considerably flatter than the H_2N-C group in H_2NCN . This should result in a lower inversion barrier for the NH₂ group in H₂N₃⁺, which is also apparent from the lowering of the frequency of the NH₂ wagging mode, $\nu_6(A')$, which, on the basis of its symmetry coordinate and potential energy distribution, represents the inversion motion (see below).

Vibrational Spectra. Infrared and Raman spectra were recorded for $H_2N_3^+SbF_6^-$, $H_2N_3^+AsF_6^-$, and $H_2N_3^+BF_4^-$ (see Figures 3–5). Table VII shows the observed frequencies and their assignments.

Approximate mode descriptions, symmetry coordinates, and potential energy distributions for $H_2N_3^+$ and isoelectronic $H_2N\dot{C}N$ are included in Table V. The LDF force fields for H₂N₃⁺ and H₂NCN were analyzed in terms of internal coordinates and are given in Table VI.

Although cyanamide, H2NCN, is a simple molecule of great industrial importance and its structure is well-known from microwave spectroscopy, 20,30,31 its vibrational analysis is still incomplete. This is partially due to experimental difficulties, i.e. its low vapor pressure and tendency to polymerize, and to complications caused by its low inversion barrier at the nitrogen atom.

The H₂NCN molecule and the isoelectronic H₂N₃⁺ cation possess symmetry C_s , and their nine fundamental vibrations are classified as $\Gamma = 6A' + 3A''$ (see Table V). Of the nine fundamental vibrations of H2NCN, the antisymmetric NH2 deformation, $\nu_8(A'')$, has not been experimentally observed, the two NCN bending modes, $\nu_5(A')$ and $\nu_9(A'')$, have been observed only in the liquid phase²⁸ or solution,²⁴ and the NH₂ wagging mode, $\nu_6(A')$, is complicated by inversion splittings.²¹ Nevertheless, H₂NCN served as a good case for testing the accuracy of the LDF calculations. As can be seen from Table V, our LDF results for H₂NCN are in good agreement with the experimental frequencies. Consequently, the LDF values for H₂N₃⁺ should be equally good and were used as a guide for the following assignments for H₂N₃⁺.

The assignment of the two NH₂ stretching modes, $\nu_1(A')$ and $\nu_7(A'')$, the N=N stretching mode, $\nu_2(A')$, and the NH₂ scissoring mode, $\nu_3(A')$, to the bands at about 3170, 3280, 2318, and 1547 cm⁻¹, respectively, is unambiguous. In the 1100-1300-cm⁻¹ region, two bands are observed at about 1129 and 1259 cm⁻¹, respectively, which, on the basis of the LDF predictions, should represent the N-N stretching mode, $\nu_4(A')$, and the antisymmetric NH₂ deformation, $\nu_8(A'')$, respectively. This choice of assignments is also supported by the observations that the 1259-cm⁻¹ mode is more intense in the infrared and less intense in the Raman spectra and that, in the room-temperature Raman spectrum of H₂N₃⁺SbF₆⁻, it is broadened so much that it is no longer observable. A similar broadening of the Raman bands at ambient temperature has also been observed for the remaining NH2-group modes in the H₂N₃+SbF₆ spectrum. This positive identification of the antisymmetric NH₂ deformation vibration for H₂N₃⁺ suggests that, in H₂NCN, this mode should occur in a similar frequency range and might either by assigned to the broad band at about 1150 cm⁻¹ in the infrared spectrum of liquid H₂NCN,²⁷ or, in the gas phase, coincide with the N-C stretching mode at 1055 cm⁻¹.

The remaining three, yet unassigned, fundamental vibrations are the NH_2 wagging mode, $\nu_6(A')$, and the two N_3 skeletal deformation modes, $\nu_5(A')$ and $\nu_9(A'')$. On the basis of the LDF calculations, these three modes are expected to occur in the

400-500-cm⁻¹ frequency range, which is complicated by bands due to the anions. Futhermore, the A" skeletal bending mode, ν_9 , is expected to be of very low infrared intensity,²³ and the NH₂ wagging mode, $\nu_6(A')$, should not exhibit any inversion splittings since in the crystallinic salts the hydrogens are locked into fixed positions by fluorine bridges (see X-ray crystal structure section).

Inspection of the low-temperature Raman spectra of $H_2N_3^+$ SbF₆ and H₂N₃+AsF₆ reveals a reasonably intense band at 410-420 cm⁻¹, which has a very weak counterpart in the infrared spectra and is only slightly broadened at room temperature. Hence, this vibration should belong to one of two skeletal bending modes of H₂N₃⁺. Since, in the Raman spectra of liquid^{24,28} or dissolved²⁴ H₂NCN, the out-of-plane NCN deformation mode has by far the highest intensity of the three modes in question and the 410-420-cm⁻¹ frequency value is very close to that of 429 cm⁻¹ calculated by us for the out-of-plane N₃ deformation mode of H₂N₃⁺, this 410-420-cm⁻¹ band can be assigned with confidence to the $\nu_9(A'')$ mode of $H_2N_3^+$.

The two remaining A' modes, ν_5 and ν_6 , are more difficult to assign. In view of their similar predicted frequencies (530 and 489 cm⁻¹) and related motions, we expect their symmetry coordinates to be strongly mixed (see PED of Table V), i.e. to be symmetric and antisymmetric combinations of S_5 and S_6 . Both modes are expected to be of low Raman³² but significant infrared intensity²⁴ and, therefore, should be detectable in the infrared spectra. The infrared spectrum of $H_2N_3^+SbF_6^-$ shows a shoulder at 530 cm⁻¹ and a medium weak band at 489 cm⁻¹, and that of $H_2N_3^+AsF_6^-$ shows a medium band at 538 cm⁻¹. In $H_2N_3^+BF_4^-$, the 530-cm⁻¹ region is obscured by the antisymmetric BF₄⁻ deformation, $\nu_4(F_2)$. Consequently, the ν_5 and ν_6 modes of $H_2N_3^+$ are tentatively assigned to the bands at about 530 and 489 cm⁻¹, respectively.

The above assignments can account for all the observed features in the vibrational spectra of the H₂N₃⁺ salts, except for a medium weak band at 900 cm⁻¹ and a shoulder at 820 cm⁻¹ in the infrared spectrum of H₂N₃+AsF₆. These two features are of variable intensity and show no counterparts in the IR spectrum of H₂N₃+SbF₆. Therefore, they are judged to be due to an unknown

In the low-temperature Raman spectra of H₂N₃+SbF₆ and $H_2N_3^+AsF_6^-$, the anion bands become much more complex than those in the room-temperature spectra. This is attributed to the freezing out of ion rotation, which for the anions causes splittings into degenerate components and violations of the O_h selection rules, as shown by the observation of the ν_6 mode for AsF₆. In addition, the low-temperature Raman spectrum of H₂N₃+SbF₆ shows two bands at 332 and 259 cm⁻¹, which probably are not due to the SbF₆⁻ anion but represent H...F bridge bonds. This temperature effect on the vibrational spectra might also cause a significant broadening of the NH₂ wagging band, ν_6 , at room temperature and, thereby, contribute to the difficulty of observing this mode in our infrared spectra.

In summary, the nine fundamental vibrations of $H_2N_3^+$ have been observed with frequencies which are in very good agreement with our LDF calculations. This confirms the asymmetric nonplanar aminodiazonium structure of H₂N₃⁺, found by the X-ray crystal structure determination. The previous failure⁵ to observe most of these bands for H₂N₃+SbCl₆⁻ is attributed to their relatively low infrared intensities and relative broadness at room temperature.

Normal-Coordinate Analysis. To support our vibrational assignments for H₂N₃⁺, normal-coordinate analyses were carried out for H₂N₃⁺ and isoelectronic H₂NCN (see Tables V and VI) with the LDF force fields. The corresponding frequencies and symmetry coordinates are listed in Table V. Our LDF force field for H_2NCN is in good general agreement with that previously published²⁴ by Ichikawa et al. at the 4-31G* level of theory, if it is kept in mind that the frequencies at the 4-31G* level are on average about 10% higher than the experimental ones. The potential energy distributions are given in Table V and support the given mode descriptions.

A special comment is required on the magnitudes of F_{99} in our force fields, which are given in Table VI. The listed F_{99} values are clearly too high and should be comparable to those of F_{55} . The $\nu_5(A')$ and $\nu_9(A'')$ modes represent the in-plane and outof-plane deformations of the nearly linear NXN groups, which, therefore, should be almost degenerate and exhibit similar frequencies and force constants. Whereas the frequencies of ν_9 are comparable to those of ν_5 , the F_{99} values in Table VI are about 2-4 times larger than those of F_{55} . This is an artifact caused by the inability to exactly describe with our computer input code the S₉ symmetry coordinate of the out-of-plane NXN deformation for these molecules when they possess a slightly bent NXN group. Our program to convert the Cartesian second derivatives to symmetry-adapted internal coordinates allows for only four kinds of internal motions: bond stretching, angle bending, a dihedral angle between two planes, and the minimum angle that a bond forms with a plane. Thus, the $\nu_9(A'')$ mode had to be defined as the sum of the angles formed between the X-N(2) bond and the two planes defined by H(1)N(1)X and H(2)N(1)X. By making the NXN bonds linear, we were able to properly describe S_9 with this code and obtain values for F_{99} (H₂N₃⁺, 0.47 mdyn/Å; H₂N-CN, 0.44 mdyn/Å) that are in excellent agreement with our expectations (see above) and those previously reported.²⁴ The PED (94S₉ + 6S₈) for the revised F_{99} values was similar to those given in Table V, while the remainder of the A" force field remained practically unchanged.

Acknowledgment. The authors thank Dr. C. J. Schack and Mr. R. D. Wilson for their help, Dr. R. Minkwitz for bringing his unpublished studies on $\rm H_2N_3^+SbCl_6^-$ to our attention, and the U.S. Army Research Office and the U.S. Air Force Phillips Laboratory for financial support of the work at Rocketdyne. T.M. thanks the Deutsche Forschungs Gemeinschaft for the provision of a postdoctoral fellowship.

The Vanadium(IV) Enterobactin Complex: Structural, Spectroscopic, and Electrochemical Characterization¹

Timothy B. Karpishin, Torin M. Dewey, and Kenneth N. Raymond*

Contribution from the Department of Chemistry, University of California, Berkeley, California 94720. Received August 24, 1992

Abstract: The siderophore enterobactin (H₆ent) has been crystallized as the vanadium(IV) complex in the compound K₂[V(ent)]-3DMF from dimethylformamide (DMF) solution. The pseudooctahedral coordination of the metal ion is through the three catechol groups and has approximate C_3 molecular point symmetry. The geometry is intermediate between trigonal prismatic and octahedral, with a twist angle of 28°. For comparison, the unconstrained complex of N-ethyl-2,3-dihydroxybenzamide (H₂eba) has been determined. The twist angle in [V(eba)₃]²⁻ is 36°, somewhat larger than in the constrained enterobactin complex. The other metrical parameters are essentially identical between the two. Both the stability and the Δ chirality of the enterobactin complex are explained as due to the conformation of the triserine backbone. Molecular modeling calculations correctly predict this chiral preference as well as that for the complex of the (linear trimer) enterobactin hydrolysis product. The V-O bond distances in [V(ent)]² average 1.946(7) and 1.939(5) Å to the ortho and meta catechol oxygens, respectively. Hydrogen bonding between the amide proton and the ortho catechol oxygen is an important feature of the structure. Comparison of the conformation of the trilactone serine ring in the vanadium enterobactin complex with two related trilactones shows that the conformation seen is characteristic of this triserine structure and is not a result of the metal complexation or of hydrogen bonding within the triserine ring. This also implies that the free ligand has a conformation similar to that seen in the metal complex. The potassium cations are partially coordinated by the meta catechol oxygens. Molecular modeling indicates that a smaller cation such as calcium cannot fit in the cavity formed between the octahedral catechol coordination site and the triserine ring. The UV/vis spectrum of [V(ent)]²⁻ has been assigned on the basis of earlier quantitative spectroscopic studies. The spectroscopic parameters indicate that the M-O bonding is stronger in the vanadium complex than in the iron complex of enterobactin, partially due to strong π bonding. A quasi reversible reduction potential (in DMF vs SCE) is found for the V^{V}/V^{IV} couple of +0.39 V. For $K_{2}[V(ent)] \cdot 3DMF$, space group $P2_{1}$, a = 13.164(3), b = 10.001(1), c = 16.600(2) Å, $\beta = 10.001(1)$ 93.96°, z = 2, V = 2180(1) Å³. For 5551 unique data with $F_o^2 > 3\sigma(F_o^2)$ R = 0.049, $R_w = 0.062$. For K₂[V(eba)₃]·3DMF, space group $Pa\bar{3}$, a = 20.632(5) Å, z = 8, V = 8783(5) Å³. For 2526 unique data with $F_o^2 > 3\sigma(F_o^2)$ R = 0.051, $R_w = 0.058$.

Introduction

Most aerobic and anaerobic bacteria synthesize and excrete low molecular weight compounds (siderophores) for the solubilization and transport of iron.²⁻⁴ Since the iron supply is often a limiting factor in the growth of these microbes, siderophores and their corresponding transport systems play an important role in bacterial virulence.⁵ Of the approximately 200 siderophores now discovered, enterobactin (Figure 1), produced by enteric bacteria such as *Escherichia coli*, has received considerable at-

tention. Since its discovery in 1970,^{6,7} the synthesis,⁸⁻¹⁰ biosynthesis,¹¹ microbial transport,^{5,12-14} and solution thermodynamics¹⁵⁻¹⁷
