Just Accepted

"Just Accepted" manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides "Just Accepted" as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. "Just Accepted" manuscripts appear in full in PDF format accompanied by an HTML abstract. "Just Accepted" manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). "Just Accepted" is an optional service offered to authors. Therefore, the "Just Accepted" Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the "Just Accepted" Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these "Just Accepted" manuscripts.

Abstract

We report the synthesis of high-quality single crystals of ReS₂ and ReSe₂ transition metal dichalcogenides using a modified Bridgman method that avoids the use of a halogen transport agent. Comprehensive structural characterization using x-ray diffraction and electron microscopy confirm a distorted triclinic 1T' structure for both crystals, and reveal a lack of Bernal stacking in ReS₂. Photoluminescence measurements on ReS₂ show a layer independent bandgap of 1.51 eV, with increased PL intensity from thicker flakes, confirming interlayer coupling to be negligible in this material. For ReSe₂, the bandgap is weakly layer dependent and decreases from 1.31 eV for thin layers to 1.29 eV in thick flakes. Both chalcogenides show feature-rich Raman spectra whose excitation energy dependence was studied. The lower background doping inherent to our crystal growth process results in high field effect mobility values of 79 cm²/Vs and 0.8 cm²/Vs for ReS₂ and ReSe₂ respectively, as extracted from FET structures fabricated from exfoliated flakes. Our work shows ReX₂ chalcogenides to be promising 2D materials candidates, especially for optoelectronic devices, without the requirement of having monolayer thin flakes to achieve a direct bandgap.

Introduction

The rhenium-based dichalcogenide materials ReX_2 (X = S, Se) are relatively unexplored members of the class of layered transition metal dichalcogenides (TMDC) that have attracted recent research interest¹⁻⁸ due to their unique structural and electronic properties. Most of the well-established TMDCs like MoS_2 and WS_2 have interesting electronic and optical properties⁹ that make them ideally suited for a range of device applications.¹⁰⁻¹⁵ However, these properties are strongly dependent on layer thickness with the best results typically being obtained from monolayers of these 2D materials.^{16–18} For example, in monolayer form, MoS_2 has a direct band gap, but the band gap turns indirect with increasing number of layers.^{19,20} This puts severe constraints on the versatility of such TMDC materials for optoelectronic device fabrication where a direct bandgap, and sufficient active region thickness are important. Recently, ReS_2 was shown to behave as a stack of electronically and vibrationally decoupled monolayers even in bulk form, with its Raman spectrum and photoluminescence properties being independent of the number of layers.^{1-3,21} This suggests that ReS_2 could offer a novel system to study mesoscopic physics of 2D systems without the limitation of obtaining large-area, monolayer-thick flakes. Interestingly, another member of the rhenium-based dichalcogenides, $\operatorname{ReSe_2}^{4,5,8}$ is isoelectronic to ReS_2 and could also have unconventional optical and electronic properties. The inherent lattice distortion in ReSe_2 makes it a suitable candidate for tuning the magnetic and optical properties via strain engineering.⁸ The crystal growth of ReX_2 is, however, a challenge since Re has one of the highest melting points of all metals whereas S and Se have relatively low melting points

and high vapour pressures. Hence these crystals are typically grown using a halogen vapour transport route using Br_2 or I_2 as a transport agent. This, however, leads to unintentional background doping and changes the electrical properties of the material. Crystals grown by the I_2 vapour transport technique are typically p-type ^{22,23} while the use of Br_2 usually results in n-type material.²³⁻²⁸ In this paper we report the growth, under appropriate conditions, of high-quality ReS₂ and ReSe₂ single crystals by a modified Bridgman method which does not involve the use of any transport agent. We perform comprehensive structural, optical, and electrical characterization of these crystals, and obtain field effect mobility values of 79 cm²/Vs and 0.8 cm²/Vs for ReS₂ and ReSe₂ respectively, significantly higher than previously reported for similar device structures.

Single Crystal Growth

Single crystals of ReS₂ and ReSe₂ were grown from the constituent elements directly via a modified Bridgman method, by a careful optimization of the growth process using an appropriate temperature profile. The growth was performed in a 2 cm diameter, 20 cm long quartz tube, which was cleaned using HF:H₂O (1:10) solution and rinsed thoroughly with distilled water prior to the growth process. This step is critical, as apart from removing impurities, the etchant also causes a slight roughening of the inner surface of the tube, which is beneficial in promoting nucleation during the growth. The constituent elements – 5N pure Re, and S/Se were weighed in the stoichiometric proportion individually, introduced into the tube and sealed under vacuum (2×10^{-6} mbar). The growth was initiated by placing the ampoule into a vertical Bridgman furnace, with the following temperature profile used to obtain single crystals of the ReX₂ materials. Initially, the temperature was increased to 1100 °C over a 72 hr period.^a Following a stabilization time of 24 hr, the temperature was very slowly decreased to 900 °C at the rate of 1 °C/hr over a period of 10 days, after which the tube

^aSince the phase diagrams for Re-S and Re-Se and melting point data are not available in the literature or in standard materials databases, we chose a temperature similar to that used for the tungsten chalcogenides.

was cooled down to room temperature at the rate of 60 °C/hr. This resulted in the formation of shiny crystals in the form of very thin plate-like flakes of hundreds of μ m thickness and approximately 4x5 mm² in lateral size. The optical micrographs and SEM images of the grown crystals are shown in the Supporting Information, Fig. S1. For measurement of layer dependent photoluminescence, Raman spectra, and electrical properties, thin sheets were mechanically exfoliated from these flakes and transferred to SiO₂-coated Si substrates for measurements.

Results and discussion

Unlike the common hexagonal (e.g. MoS_2) or octahedral (e.g. WS_2) structures seen in most TMDCs, the rhenium-based dichalcogenides, ReS_2 and $ReSe_2$ crystallize in a distorted 1T' structure having a triclinic symmetry P1. Schematic diagrams of the side and top view of such a structure are shown in Fig. 1(a) and (b), respectively. The d³ electron configuration in the outermost shell of Re is responsible for the displacement of the metal (Re) atoms from their octahedral position at the centre of the anion cage. As a result of the Peierls distortion, the Re atoms dimerize to form diamond-shaped Re chains that extend along the in-plane b-axis. This results in the ReX₂ materials crystallizing in a stable semiconducting 1T' phase with an in-plane anisotropy. The X-Re-X sandwiched layers are stacked along the c-axis by weak van-der-Waals forces to form a layered structure. We discuss the detailed characterization of these materials in the sections below.

Structural analysis

High resolution X-ray diffraction (HRXRD) measurements were used to evaluate the structural properties of the ReS₂ and ReSe₂ single crystals, the data are shown in Fig. 2(a) and (b) respectively. An expanded view of the most prominent (00l) peak is shown in the inset. For both samples, we observed only the (00l) reflections with all other (hkl) reflections Page 5 of 24

Figure 1: Schematic diagram of atomic arrangement in ReX_2 (X=S, Se): (a) side view and (b) top view along the c-axis. Here, blue and green color circles represent the transition metal and chalcogenide, respectively.

being absent, suggesting a highly-oriented single crystal in the c-axis direction. The most significant (001) peak, was observed at $2\theta = 14.5^{\circ}$ and $2\theta = 13.5^{\circ}$, for ReS₂ (Fig. 2(a)) and ReSe₂ (Fig. 2(b)), respectively. The narrow and sharp diffraction peaks, all with <0.1° FWHM values, point to the high crystalline quality of our material, showing that the conventional Bridgman method without utilizing a halogen transport agent can provide high-quality ReX₂ crystals. The crystalline quality of grown crystals were also reaffirmed from diffraction measurements using transmission electron microscopy (TEM) discussed subsequently. The detailed structural parameters such as lattice constants, FWHM, and d-spacings extracted from the measured data are presented in Table-S1 in the Supplementary Information along with powder diffraction data(Fig. S2).

Figure 2: HRXRD 2θ -scan for (a) ReS₂ and (b) ReSe₂ single crystals. The patterns were indexed with ICDD database 00-052-0818 and 04-007-1113, for ReS₂ and ReSe₂, respectively. The y axis is plotted on a log scale. Insets show expanded views of the most prominent reflection. The absence of other (hkl) reflections and the small FWHM values of 0.1° and 0.06° for (001) reflection of ReS₂ and ReSe₂, respectively, point to the high crystal quality.

Transmission electron microscopy

The detailed atomic arrangement of the ReX_2 crystals was investigated using High Resolution Transmission Electron Microscopy (HRTEM) performed using a 200 kV FEI Tecnai-20 system. Sample preparation details are described in the Supplementary Information. In order to get information about the in-plane and out-of-plane atomic arrangements, TEM images were obtained for both crystals for two orthogonal viewing axes, parallel to (cross sectional view) and perpendicular to the basal plane (top view).

Figs. 3 and 4 show HRTEM images ((a) and (c)) and the corresponding diffraction patterns ((b) and (d)) for the ReS₂ and ReSe₂ crystals, respectively. Fig. 3(a) shows the cross sectional TEM image of an ReS₂ sample; the corresponding diffraction pattern along the [-1 2 1] zone axis is shown in Fig. 3(b), with the simulated pattern shown in the inset. The diffraction patterns were simulated using the JEMS software. The absence of diffraction spots from odd planes of reflection such as (101), (303), etc., indicates a lack of Bernal stacking between the successive layers in ReS₂ which is consistent with the previously reports by Tongay et al.¹ Fig. 3(c) shows the top view of the ReS₂ along the [0 0 1] zone

Chemistry of Materials

axis, normal to the basal plane, where the Re chains can be clearly seen. The corresponding diffraction pattern and simulation are shown in Fig. 3(d). It is interesting to note that the intensity of the (2h2k0) diffraction spots are higher in intensity compared to those from the (hk0) planes, owing to an anisotropic ordering of the Re atoms, with small in-plane displacements from the equilibrium positions.

The HRTEM images and diffraction patterns for ReSe_2 are shown in Fig. 4. Similar to the case of ReS_2 , the cross-sectional view and corresponding diffraction pattern are shown in parts (a) and (b) with top view and corresponding diffraction pattern shown in parts (c) and (d). An immediate noticeable point of difference while comparing the diffraction pattern in Fig. 4(b) with that of ReS_2 in Fig. 3(b) is the presence of the diffraction spots from the odd planes of reflection (such (001), (1-21), etc.) in the ReSe_2 case, suggesting that the layers in ReSe_2 have a Bernal stacking arrangement, unlike in ReS_2 . As expected, the top view is rather similar, with the familiar Re chains being present, and the diffraction pattern pointing to an anisotropic atomic arrangement.

Figure 3: HRTEM images of ReS_2 . (a) Cross sectional view with electron beam directed parallel to the basal plane, (b) the corresponding diffraction pattern centered on the [-1 2 1] zone axis with the simulate diffraction pattern shown in the inset. Here, the absence of the diffraction spots from the (1 0 1), (3 0 3),... planes of reflection shows the lack of Bernal stacking in ReS_2 . (c) Top view, with the electron beam direction normal to the basal plane, and (d) the corresponding diffraction pattern centered on the [0 0 1] zone axis with the simulated diffraction pattern shown in the inset.

Figure 4: HRTEM images of ReSe_2 . (a) Cross sectional view with electron beam directed parallel to the basal plane, (b) the corresponding diffraction pattern centered on the [2 1 0] zone axis with the simulated diffraction pattern shown in the inset. (c) Top view, with the electron beam direction normal to the basal plane, and (d) the corresponding diffraction pattern centered on the [1 0 0] zone axis with the simulated diffraction pattern shown in the inset.

X-ray photoelectron spectroscopy

The compositional and core level elemental analysis of the crystals were characterized by energy dispersive x-ray spectroscopy (EDX) and X-ray photoelectron spectroscopy (XPS). The stoichiometry of the sample was determined from EDX analysis, where the observation of a 1:2 atomic ratio of metal (Re) to chalcogenide (S, Se) (see section-4 in SI for details) confined the formation of the ReX_2 phase. The core level elemental analysis of the valence band energy levels of the Re-atom (Fig. 3(a),(c)) shows the f-shell splitting into the $4f_{7/2}$ and $4f_{5/2}$ sub-levels with an energy difference of 2.4 eV, consistent with the expected Remetal peak splitting. However, the peak positions of the $4f_{7/2}$ and $4f_{5/2}$ features at 42.18 eV and 44.58 eV for both ReS_2 and ReSe_2 , respectively, indicate a blue shift by 1.68 eV in comparison to the standard position 29 of the 4f core level peaks of metallic Re at 40.5 eV and 42.9 eV. Such energy shifts of the 4f levels could be due to the bonding of chalcogens atoms to rhenium in the ReX₂. In the case of chalcogens, the 2p core level peaks, $2p_{3/2}$ and $2p_{1/2}$ of S atom, and 3d core level peaks, $3d_{5/2}$ and $3d_{3/2}$ of Se atoms are located at 161.58 eV and 167.28 eV, and 55.48 eV and 56.28 eV, respectively, consistent with the reported work on bulk ReS_2 .³⁰ The details of the peak positions and corresponding linewidths are listed in Supplementary Information (Table-S6).

Figure 5: XPS spectra of the ReS₂ and ReSe₂ crystals. The core level 4f-shell peaks, $4f_{7/2}$ and $4f_{5/2}$ of the Re atom for (a) ReS₂ and (c) ReSe₂. The chalcogens' outer shells are, $2p_{3/2}$ and $2p_{1/2}$ core levels for the (b) S 2p feature, and $3d_{5/2}$ and $3d_{3/2}$ core levels for the (d) Se 3d feature.

Raman spectroscopy

The atomic vibrational spectra of layers exfoliated from the ReS₂ and ReSe₂ crystals were recorded using three different laser excitation wavelengths, 514 nm, 532 nm, and 633 nm to understand the wavelength-dependent behavior of the Raman modes. The exfoliation was carried out mechanically using scotch tape with the layers being transferred to silicon substrates coated with a 300 nm thick thermal oxide layer on top of it. All the measurements were recorded at room temperature. The laser power was kept at 0.5 μ W to avoid heating the samples. The Raman spectra of 2 nm thick flakes of ReS₂ and ReSe₂, excited at different laser wavelengths, are shown in Fig.6 (a) and (b). Unlike other members of TMDCs such

as MoX₂ and WX₂, the Raman spectra of the Re-based dichalcogenides are feature-rich with about 18 first-order Raman active modes in the range of 100-300 $\rm cm^{-1}$ which are non-degenerate because of their low symmetry structure. Interestingly, they exhibit novel vibrational properties such as the absence of active in-plane vibrational modes E_2g^1 and E_2g^2 (Fig.6) mode below $\leq 100 \text{ cm}^{-1}$ due to the presence of only one layer in their unit cell rather than two in MoS_2 or three in WS_2 unit cell, respectively. All expected active in-plane and out-of plane vibrational modes along with the contracted mode of Re, S and Se are observed. Two intense and characteristic vibration modes are observed at 150 $\rm cm^{-1}$ and 212 $\rm cm^{-1}$ for the ReS_2 and 124 cm^{-1} and 158 cm^{-1} in the case of ReSe_2 which is consistent with the literature.^{1-4,31} The observed in-plane and out of plane vibrations are reasonable agreement with the recent simulated and experimental values reported by Feng et. al.³ The in-plane vibrational modes appear at 156 cm⁻¹, 168.4 cm⁻¹, 212.2 cm⁻¹, and 236.8 cm⁻¹ for Re-atoms and 308.2 cm^{-1} , and 313.5 cm^{-1} in the case of S-atoms. The same matching was observed for out-of plane vibrations located at, 133.1 cm^{-1} , 141.9 cm^{-1} and 421.7 cm^{-1} , 445.8 cm^{-1} for Re and S atom, respectively along with the contracted vibrations of Re-S atoms, 275.1 cm^{-1} , and 280.4 cm⁻¹. Apart from the difference in the outer most electron configuration, ReSe_2 belongs to the same structure formation as ReS_2 , and as expected shows nearly same number of active vibrational modes in its Raman spectrum, as seen in Fig. 6(b). Comparative Raman spectra for layers of different thickness are shown in Supporting Information section-5.

Figure 6: The normalized Raman scattering spectra measured at 514 nm, 532 nm, and 633 nm excitation energy for exfoliated (a) ReS_2 and (b) ReSe_2 on a SiO_2/Si substrate. The thickness of the flake was ~ 2 nm.

Photoluminescence measurements

The dependence of photoluminescence (PL) properties with sample thickness provides a simple way to verify the weak interlayer coupling in the 1T' stucture, and check for a cross-over from direct to indirect band gap. Fig. 7(a) shows the room temperature PL spectra from exfoliated ReS₂ flakes of two different thickness, denoted as the thin (~2 nm) and thick (~10 nm) samples. The PL peaks were observed at the same energy position, 1.51 eV, for both thin and thick flakes, consistent with the previously reported values for the bulk.¹ Further, the peak intensity is higher for the thicker layer than thinner one, as was also reported in Ref.(1,7). This is in sharp contrast to the typical behavior seen in Mo and W-based TMDCs and confirms that ReS₂ behaves as a stack of decoupled monolayers even in bulk form. In the case of ReSe₂, the corresponding PL spectra for thick and thin samples are shown in Fig. 7(b). The peak position shifts slightly from 1.31 eV for the thin layer to 1.29 eV for the thick layer. This is similar to the report by Zhao et. al.³² (\approx 1.27 eV for 10L and \approx 1.32 eV for 2L), and also agrees with the observations of Yang et. al.⁸ (\approx 1.44 eV for a monolayer flake, with much of the blueshift with reducing thickness occurring close to the one ML limit).

Further, the intensity of the luminescence is also weaker for the thicker layer. However the drop in luminescence with thickness is not as drastic as that for the Mo- and W-based TMDCs, suggesting that there is a very weak, but non-negligible interlayer coupling. Unlike MoS_2 , the presence of structural distortion results in a lesser charge difference between the Re-layer and chalcogens (S,Se) layers leading to a weaker inter-layer interaction in ReX₂. These observations are consistent with the structural information evaluated from XRD and electron microscopy reported in the earlier sections where the presence of structural distortion is lesser in ReSe₂ compared to ReS₂.

Figure 7: Room temperature PL spectra of thin (~ 2 nm) and thick (~ 10 nm) flakes of (a) ReS₂ and (b) ReSe₂. The flakes were exfoliated onto a SiO₂/Si substrate and a 633 nm laser was used for excitation.

Electrical measurements

Electrical properties of the ReS₂ and ReSe₂ crystals were evaluated by characterizing thinfilm field effect transistors (FET) fabricated on mechanically-exfoliated flakes transferred to a 300 nm SiO₂ coated p^{++} Si wafer. Thin flakes were identified by optical contrast and AFM. FETs were fabricated with these flakes as channel using standard lithography techniques. Source and drain contacts were defined by thermal evaporation of 10/70 nm Cr/Au followed by lift-off in acetone. The transfer characteristics for ReS₂ and ReSe₂ devices are

shown in Fig. 8 (a) and (b), respectively, with optical images of the fabricated devices shown in the insets. $I_{ds}-V_{ds}$ curves are provided in the Supporting Information. On performing electrostatic gating, ReS₂ and ReSe₂, both, are observed to be n-type. For ReSe₂, this behavior is contrary to previous reports.⁵ We attribute this to the absence of a transport agent, like I₂, during the growth process, which can cause charge compensation. We extract field-effect mobility from the linear part of the gating curve using the formula $\mu_{FE} =$ $(dI_{ds}/dV_g)\times(L/W)\times(1/(\epsilon_{ox}V_{bias}))$, where ϵ_{ox} is the capacitance per unit area between channel and back-gate. For our case, $\epsilon_{ox} = 1.15 \times 10^{-4} \text{ F/m}^2$. The mobility for ReS₂ is calculated to be 79.1 cm²/Vs, while for ReSe₂ it is 0.8 cm²/Vs. The mobility values for the two materials are significantly higher than those previously reported values for multi-layered ReS₂ (15.4 cm²/Vs)³³ and ReSe₂ (0.10 cm²/Vs)⁵ FETs, again reflecting the improved crystal quality. A summary of mobility values obtained by various groups is presented in Table 1. We report an I_{on}/I_{off} of 2.7×10³ for ReS₂ and 3.0×10⁴ for ReSe₂. The transconductance of the device is observed to be 780 nS/ μ m and 0.11 nS/ μ m for ReS₂ and ReSe₂, respectively.

Figure 8: Electrical characterization $(I_{ds}-V_{bg})$ of FET structures: Room temperature transfer characteristics at $V_{ds} = 200$ mV for (a) ReS₂ and (b)ReSe₂. The insets show optical images of the devices, the scale bar is 10 μ m in both images. The two steps in the curve for ReS₂ arise from the flake having regions of two different thicknesses. See Supporting Information for an enlarged view of the device.

Conclusion

Using a modified Bridgman method, we have successfully grown high-quality single crystals of ReS₂ and ReSe₂ without the use of a halogen transport agent. The crystals were comprehensively characterized using HRXRD and TEM, which revealed a distorted triclinic 1T' structure for both crystals. However, the lack of Bernal stacking in ReS₂ was confirmed from the HRTEM. Both chalcogenides show rich Raman spectra whose excitation energy dependence was studied. Photoluminescence measurements revealed a layer independent bandgap value of 1.51 eV for ReS₂, with increased PL intensity for thicker flakes, thus confirming the absence of interlayer coupling in this material. For ReSe₂, the bandgap decreased from 1.31 eV for thin layers to 1.29 eV in thick flakes, suggesting a non-neglible interlayer interaction, which is however weaker than the usual Mo and W based TMDCs. Electrical measurements on FETs fabricated show a remarkably improved field effect mobility due to the lower background doping. Our studies confirm the recently observed atypical properties of these materials, and show the ReX₂ series to be useful candidates for optoelectronic TMDC devices without the necessity to achieve monolayer thin flakes of the materials.

Supporting Information

Optical and SEM images of crystals; powder XRD profiles and analysis; additional TEM images; compositional analysis using EDX and XPS; additional Raman, PL and electrical measurements.

Methods

Mechanical Exfoliation of ReX ₂

Few-layer ReX_2 nanosheets were exfoliated mechanically using scotch tape from bulk ReS_2 and ReSe_2 single crystals individually and transferred to doped-Si substrates covered with thermally-deposited oxide of 300 nm thickness.

XRD, EDX and XPS analysis

The high resolution X-ray diffraction and the powder X-ray diffraction were measured using Panalytical X'Pert Pro system for single crystal and powder samples, respectively, using a CuK_{α} source, and a step size of 0.016°. The EDX measurement was done using an Oxford Inca Energy EDS. The core level elemental analysis of the present elements was carried out using an X-ray photoelectron spectroscope (AXIS ULTRA-DLD, Shimadzu) with AlK_{α} source using an X-ray monochromator. The surface morphology of the as-grown crystals was observed by scanning electron microscopy using a Zeiss Ultra FESEM at an accelerating voltage of 5 kV. Transmission electron microscopy (TEM) was carried out using a FEI Tecnai 20 at an operating voltage of 200 kV (filament: LaB₆). For sample preparation for in-plane view, bulk flakes were stuck face-to-face using G1 epoxy and cured at 130 °C for 15 min. This sandwich material was placed in a slotted Ti grid and again cured at 130 °C for 5 min. The sample was next thinned down upto 80-100 μ m by polishing from both sides of the disc. After making a dimple of around 20 μ m, sample was ion-milled at 3 kV till a hole appeared at the center. As a final step, it was polished at 0.5 kV till the region around the hole became thin enough to be electron transparent.

Raman and PL measurements

To understand the layer dependent atomic vibrational properties of the ReX₂ samples, the Raman measurement was carried out on different thickness flakes, thin flake (\sim 2 nm) and thick flake (\sim 10 nm), at three different laser excitation wavelengths (Fig. S6). The Raman signals at 514 nm, and 633 nm wavelengths were measured using a Renishaw PL/Raman system, whereas, the 532 nm wavelength measurement was recorded using a Witec alpha 300R confocal Raman microscope. The variation of the bandgap with the number of layers was also checked using photoluminescence(PL) spectroscopy. The luminescence was measured at three different excitation wavelengths, 514 nm, 532 nm, and 633 nm, for both ReS₂ and ReSe₂. All the measurements were carried out at room temperature.

Device fabrication

FET devices were demonstrated on mechanically-exfoliated flakes transferred to 300 nm SiO₂-coated heavily-doped Silicon wafers using the scotch-tape technique. Thin flakes were

identified by optical contrast and AFM. FETs were fabricated with these flakes as channel using standard electron beam lithography techniques. Contacts of Cr/Au (10 nm/70 nm) were realized by thermal evaporation at ≈ 5 Å/s followed by liftoff in acetone. All electrical measurements were performed on wire-bonded samples in a home-made measurement setup under vacuum condition ($\leq 10^{-5}$ mbar) at room temperature in dark.
