DOI: 10.1039/c1dt10612k

The electronic and local structures of partially anion-substituted lithium manganese spinel oxides as positive electrodes for lithium-ion batteries were investigated using X-ray absorption spectroscopy (XAS).  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.018, 0.036, 0.055, 0.073, 0.110, 0.180$ ) were synthesized by the reaction between  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  and  $\text{NH}_4\text{HF}_2$ . The shift of the absorption edge energy in the XANES spectra represented the valence change of Mn ion with the substitution of the low valent cation as  $\text{Li}^+$ ,  $\text{Ni}^{2+}$ , or  $\text{F}^-$  anion. The local structural change at each compound with the amount of a Jahn–Teller  $\text{Mn}^{3+}$  ion could be observed by EXAFS spectra. The discharge capacity of the tested electrode was in the order of  $\text{LiMn}_2\text{O}_4 > \text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036$ )  $> \text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  while the cycleability was in the order of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036$ )  $\approx \text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4 > \text{LiMn}_2\text{O}_4$ . It was clarified that  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  has a good cycleability because of the anion doping effect and simultaneously shows acceptable rechargeable capacity because of the large amount of the Jahn–Teller  $\text{Mn}^{3+}$  ions in the pristine material.

## 1. Introduction

Lithium-ion batteries (LIB) with high energy density, safety, and durability are required for electric vehicles (EV), hybrid electric vehicles (HEV), and plug-in hybrid electric vehicles (PHEV) as their power sources. Lithium manganese spinel oxide  $\text{LiMn}_2\text{O}_4$  is one of the candidates for the positive electrode materials for LIBs as an alternative to the conventional  $\text{LiCoO}_2$  cathode because of its low cost and low toxicity.<sup>1,2</sup> However, the capacity fading during the charge-discharge cycle is one of the serious problems. It is thought that this phenomenon is caused by the disproportional reaction of  $\text{Mn}^{3+}$  accompanied with dissolution of  $\text{Mn}^{2+}$  into the electrolyte, unstable surface structure of  $\text{LiMn}_2\text{O}_4$  at charged states, or local structural distortion of  $\text{MnO}_6$  octahedra by the Jahn–Teller effect.<sup>3,4</sup> Several research groups have investigated the electrochemical properties of partially cation-doped lithium manganese spinel oxides  $\text{LiMn}_{2-x}\text{M}_x\text{O}_4$  ( $M = \text{Li}, \text{Al}$  or the other transition metals such as  $\text{Cr}$  and  $\text{Ni}$ )<sup>5–13</sup> and shown that the

cycleability is improved with the cation doping. The average structure, the local structure, and the electronic structure and their relationships with electrochemical properties have been investigated for these cation-doped lithium manganese spinel oxides by using X-ray diffraction measurement (XRD) and X-ray absorption spectroscopy (XAS) technique. However, this cation doping increases the average oxidation state of Mn from 3+ to 4+, leading to the decrease of the reversible capacity. In other word, the increase of  $\text{Mn}^{3+}$  in the pristine material is directly linked with the increase of the reversible capacity. Hence, it is desirable to decrease the average oxidation state of Mn (increase the amount of  $\text{Mn}^{3+}$ ) while remaining good cycleability owing to the cation doping effect.

Anion-substitution has not been well studied for the lithium manganese spinel oxides compared with the cation-substitution. The radius of  $\text{F}^-$  is close to that of  $\text{O}^{2-}$ , and the electronegativity of fluorine is the largest of all elements. Hence, the substitution of  $\text{O}^{2-}$  by  $\text{F}^-$  can occur and would change the structure and electrochemical properties of lithium manganese spinel oxides. If  $\text{O}^{2-}$  is substituted by  $\text{F}^-$ , the average oxide state of Mn can be decreased and reversible capacity can be increased. In regard to cathode materials such as  $\text{LiNiO}_2$  and  $\text{LiCoO}_2$  for LIBs, there are some reports about the substitution of  $\text{O}^{2-}$  by  $\text{F}^-$ .<sup>14,15</sup> It has been reported that  $\text{LiF}$  is added to the starting materials as a fluorine source and the resulting  $\text{LiNiO}_2$  and  $\text{LiCoO}_2$  show better cycleability. For lithium manganese spinel oxides, there are also some reports about  $\text{F}^-$ -substitution. A

F<sup>-</sup>-substitution method by surface fluorination of LiMn<sub>2</sub>O<sub>4</sub> has been carried out by Yonezawa *et al.*<sup>16</sup> In their report, LiMn<sub>2</sub>O<sub>4</sub> has been treated with F<sub>2</sub> gas at various temperatures and it has been confirmed by X-ray photoelectron spectroscopy that the surface of LiMn<sub>2</sub>O<sub>4</sub> has been fluorinated. Under the optimal fluorination condition, both discharge capacity and cycleability of the surface fluorinated LiMn<sub>2</sub>O<sub>4</sub> has been better than the pristine LiMn<sub>2</sub>O<sub>4</sub>. The F<sup>-</sup>-substitution in the bulk LiMn<sub>2</sub>O<sub>4</sub> have been carried out by Amatucci *et al.*<sup>17</sup> They have synthesized Li<sub>1+x</sub>Mn<sub>2-x</sub>O<sub>4-δ</sub>F<sub>z</sub> and Li<sub>1+x</sub>Al<sub>y</sub>Mn<sub>2-x-y</sub>O<sub>4-δ</sub>F<sub>z</sub> by adding LiF to the starting materials and firing at a high temperature (800 °C). The resulting spinel oxyfluoride exhibits higher discharge capacity and better cycleability than LiMn<sub>2</sub>O<sub>4</sub>. However, it has been reported that the amount of fluorine in spinel oxyfluoride is influenced by the firing temperature and the amount of fluorine is limited at high firing temperatures at which LiF can react.<sup>18</sup> Hence, lowering the firing temperature should be important to increase the fluorine content. Recently, Choi *et al.* reported the synthesis of spinel oxyfluoride such as LiMn<sub>1.8</sub>Li<sub>0.1</sub>Ni<sub>0.1</sub>O<sub>3.927</sub>F<sub>0.073</sub> at a low temperature (450 °C) by using spinel compounds and NH<sub>4</sub>HF<sub>2</sub> as the starting materials.<sup>19,20</sup> In their reports, resulting spinel oxyfluoride shows superior electrochemical performance compared to LiMn<sub>2</sub>O<sub>4</sub>. These various reports are quite interesting, since anion substitution shows the possibility to enhance the performance of the spinel lithium manganese oxides. In order to get the guide to improve the superior electrochemical properties, understanding the detailed local/electronic structures of spinel oxyfluoride is essential. In contrast to the cation-doped compounds, such detailed structures have not been clarified for anion-substituted lithium manganese spinel oxides.

In the present paper, the local and electronic structures of the partially F<sup>-</sup>-substituted cation-doped lithium manganese spinel oxides have been respectively investigated by X-ray absorption near-edge structure (XANES) and extended X-ray absorption fine structure (EXAFS) techniques to clarify the relationship between the detailed structures and the discharge capacity profiles.

## 2. Experimental procedure

LiMn<sub>2-x</sub>Li<sub>x</sub>O<sub>4</sub> ( $x = 0, 0.05, 0.10, 0.15$ ) and LiMn<sub>1.9-y</sub>Li<sub>0.1</sub>Ni<sub>y</sub>O<sub>4</sub> ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) were synthesized by the solid-state reactions. Li<sub>2</sub>CO<sub>3</sub> (99.99% Kojundo Chemical Lab Industries), NiO (99.9% Furuuchi Chemical Industries), and Mn<sub>2</sub>O<sub>3</sub> obtained by pre-heating of MnCO<sub>3</sub> (99.99% Kojundo Chemical Lab Industries) at 600 °C for 48 h were used as starting materials. Required amounts of starting materials were mixed and heated at 800 °C for 2 days in air, and then cooled with a rate of 0.5 °C/min. For partial fluorine substitution, the obtained LiMn<sub>1.9</sub>Li<sub>0.1</sub>Ni<sub>0.1</sub>O<sub>4</sub> and NH<sub>4</sub>HF<sub>2</sub> were mixed, and then fired at 450 °C for 5 h in air.<sup>20</sup> Powder X-ray diffraction measurement (RINT-2200V) with Cu-K $\alpha$  radiation equipped with a graphite monochromator was used to examine the crystal structure of resulting materials. All the XRD analysis operated in the Bragg-Brentano geometry mode. XANES and EXAFS measurements were performed to investigate electronic and local structures of resulting materials on BL-7C<sup>21</sup> and BL-11A<sup>22</sup> at Photon Factory, High Energy Accelerator Research Organization Tsukuba, Japan.

For Mn and Ni K-edge, the appropriate amount of each sample for XANES and EXAFS measurements was mixed with boron

nitride (BN) to obtain optimum absorption jump ( $\Delta\mu t = 1$ ), and the mixture was pressed into pellets for the measurement. The spectra were recorded by the transmission mode using Si(111) double monochromators and a Rh-coated mirror for harmonic rejection except that they were recorded in a high-vacuum chamber by the total-electron-yield mode using a microchannel plate detector for Mn L-, O K- and F K-edges. Fourier transformations were performed using  $k^2$  weighting. The structural parameters were determined by curve-fitting procedures using Rigaku REX2000 data analysis software.<sup>23</sup> The effective backscattering amplitude  $F_{eff}$ , phase correction  $\gamma(k)$ , and total central atom phase shift  $\xi$  were calculated with the multiple-scattering theoretical calculation program, FEFF8.20.<sup>24</sup> The model of LiMn<sub>2</sub>O<sub>4</sub> was selected to input the starting parameters for the theoretical calculation. The  $\chi(k)$  function was fitted according to the equation:

$$\chi(k) = \sum_i \frac{N S_0^2 |f(k, \pi)| \exp(-2\sigma_i^2 k^2) \exp(-2R_i/\lambda_i) \sin[2kR_i + \phi_i(k)]}{k R_i^2} \quad (1)$$

where  $N$  is the number of neighboring atoms,  $S_0^2$  is the amplitude of  $\chi(k)$ ,  $R$  is the atomic distance to the neighboring atom,  $\sigma^2$  is the Debye–Waller (DW) factor,  $\lambda$  is the mean free path, and  $\phi$  is the total phase shift.

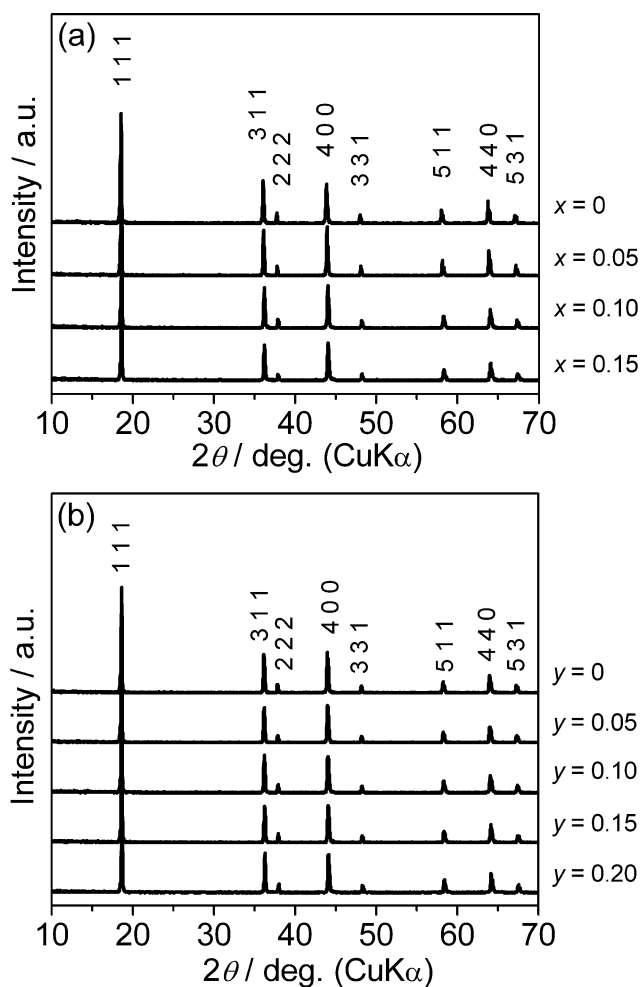

Charge-discharge measurements (1/24 C) were carried out between 3.5 and 4.3 V vs. Li/Li<sup>+</sup> at room temperature using a three-electrode cell. Li foil was used as the counter and the reference electrodes, and 1 mol dm<sup>-3</sup> LiClO<sub>4</sub>/propylene carbonate (PC) was used as an electrolyte solution. A working electrode was a mixture of 75 wt% active material, 20 wt% acetylene black, and 5 wt% polyvinylidene difluoride (PVdF) coated onto an aluminum current collector.

Delithiated powders for Ex-situ XANES and EXAFS measurements were prepared by electrochemical method by using the three-electrode cell mentioned above, except that the mixture of 70 wt% active material, 20 wt% acetylene black, and 10 wt% poly(tetrafluoroethylene) (PTFE), pressed into paste and wrapped with Ni mesh, was used as the working electrode. Electrochemical extraction of lithium ion was carried out with constant current discharge (1/12 C). Ni mesh was removed from the paste for preparing the delithiated sample. For Mn and Ni K-edge, the appropriate amount of each sample was mixed with BN to obtain optimum absorption jump ( $\Delta\mu t = 1$ ), and the mixture was pressed into pellets for the measurements.

## 3. Results and Discussion

### 3.1. Phase identification

The XRD patterns of LiMn<sub>2-x</sub>Li<sub>x</sub>O<sub>4</sub> ( $x = 0, 0.05, 0.10, 0.15$ ) and LiMn<sub>1.9-y</sub>Li<sub>0.1</sub>Ni<sub>y</sub>O<sub>4</sub> ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) are shown in Fig. 1. All peaks belonged to the spinel structure ( $Fd-3m$ ) and there were no peak of impurity. The lattice parameter was calculated from the peak top method. Fig. 2 showed the plots of the lattice parameter against the content of the low valent cation (Li<sup>+</sup> or Ni<sup>2+</sup>). In this figure, the lattice parameter was decreased monotonically with increase of low valent cation content. Taking the order of the ionic radius of Li<sup>+</sup> > Ni<sup>2+</sup> > Mn<sup>3+</sup> (according to Shannon's ionic radii<sup>25</sup>) into account, it might happen that the lattice parameter was increased with the increment of the low

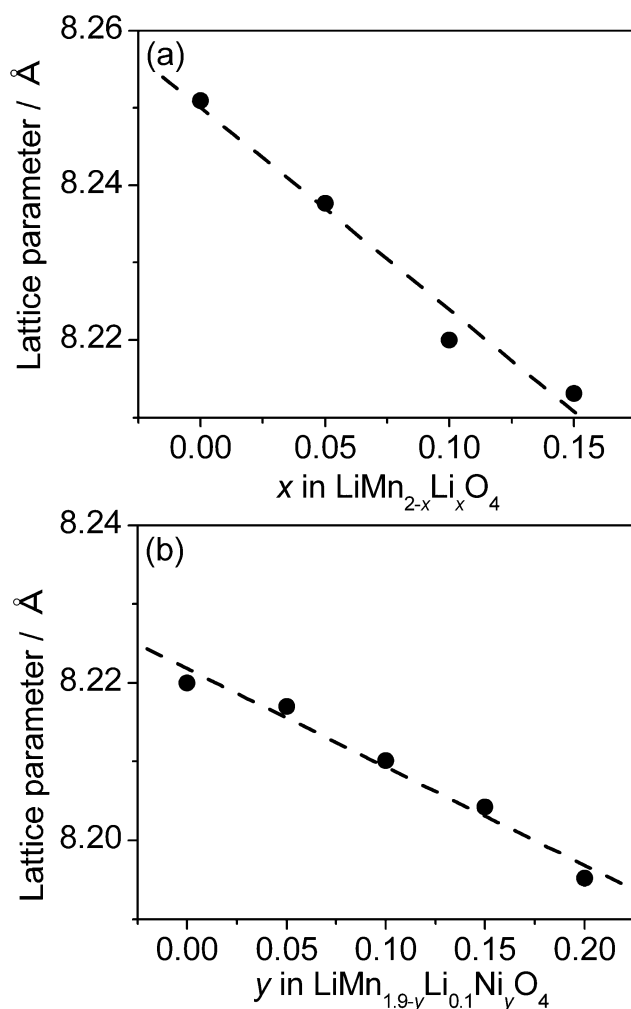

**Fig. 1** Powder XRD patterns of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) (a) and  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) (b).

valent cation content. The actually observed opposite tendency indicates that the manganese oxidation from  $\text{Mn}^{3+}$  (0.785 Å) to  $\text{Mn}^{4+}$  (0.670 Å) due to the charge compensation mainly have an effect on the lattice parameter. The XRD patterns of  $\text{F}^-$ -substituted co-cation doped lithium manganese spinel oxides  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.018, 0.036, 0.055, 0.073, 0.110, 0.180$ ) are shown in Fig. 3, in which the composition of the  $\text{F}^-$  ion was estimated with X-ray photoelectron spectroscopy (XPS). The spinel phase was observed in the composition range from  $x = 0$  to  $x = 0.073$ . For  $x > 0.073$ , an impurity peak at around  $2\theta = 30^\circ$  was observed. It has been reported that this peak has been derived from  $\text{Mn}_5\text{O}_8$ .<sup>18</sup> Fig. 4 shows the variation of the lattice parameter against the  $\text{F}^-$  content. As shown in this figure, the lattice parameter was increased monotonically with increasing the  $\text{F}^-$  content until  $\eta = 0.073$ , although the ionic radius of  $\text{F}^-$  is smaller than that of  $\text{O}^{2-}$ . When  $\text{O}^{2-}$  was replaced by  $\text{F}^-$ , the cation charge would be compensated by the reduction of  $\text{Mn}^{4+}$  to  $\text{Mn}^{3+}$ , which leads to the increased lattice parameter for the fluorinated compounds.

### 3.2. Electronic structure

The Mn K-edge XANES spectra of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) are shown in Fig. 5(a). The spectra of  $\text{MnO}_2$  and

**Fig. 2** Plots of cubic lattice parameter against content of low valent cation in  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) (a) and  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) (b).

$\text{Mn}_2\text{O}_3$  are also shown in Fig. 5(a) as references for  $\text{Mn}^{4+}$  and  $\text{Mn}^{3+}$ , respectively. In this figure, the main peak appeared at about 6550 eV represented the electron dipole transition from 1s to 4p orbital.<sup>26,27</sup> The small intensity peak appeared at around 6540 eV could be also measured, and represented the quadrupole transitions from the core Mn 1s orbital to the unoccupied Mn 3d orbital and/or the dipole transition to the hybridized Mn 4p-3d orbital.<sup>26</sup> The shape of Mn K-edge XANES spectra did not depend on the composition  $x$ , hence Mn ions are considered to exist in the octahedral 16d site.<sup>26</sup> The absorption-edge energies of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  laid between the spectra of  $\text{MnO}_2$  and  $\text{Mn}_2\text{O}_3$ , hence the Mn ions in  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  were the mixture of  $\text{Mn}^{3+}$  and  $\text{Mn}^{4+}$ . The absorption edge shifted toward large energy levels with the increase of the  $\text{Li}^+$  ion content. This result indicates that the amount of  $\text{Mn}^{4+}$  increased as suggested in the XRD result shown in Fig. 2(a). Fig. 5(b) and 5(c) show the Mn and Ni K-edge spectra of  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ), respectively. In the Ni K-edge spectra (Fig. 5(c)), there was no shift of absorption edge energy, hence the valence of Ni ion maintained divalent with the increase of the  $\text{Li}^+$  ion content. On the other hand, the absorption edge of Mn K-edge XANES spectra in  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  shifted toward large energy levels with the

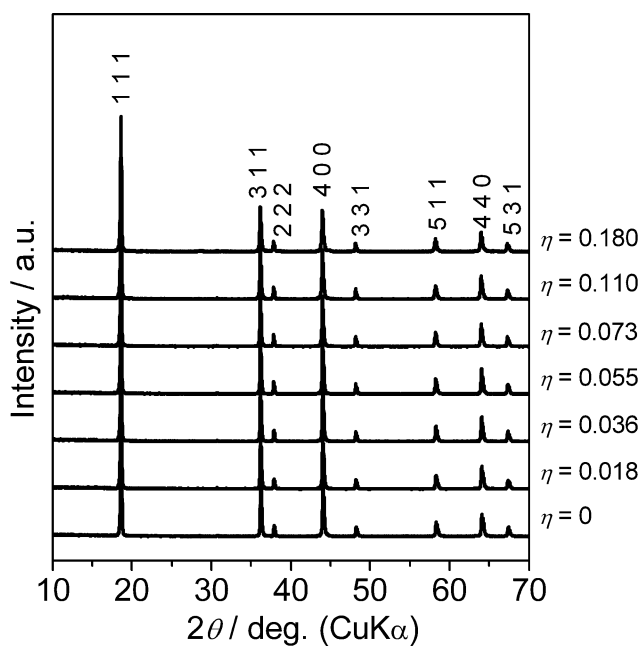

Fig. 3 Powder XRD patterns of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.018, 0.036, 0.055, 0.073, 0.110, 0.180$ ).

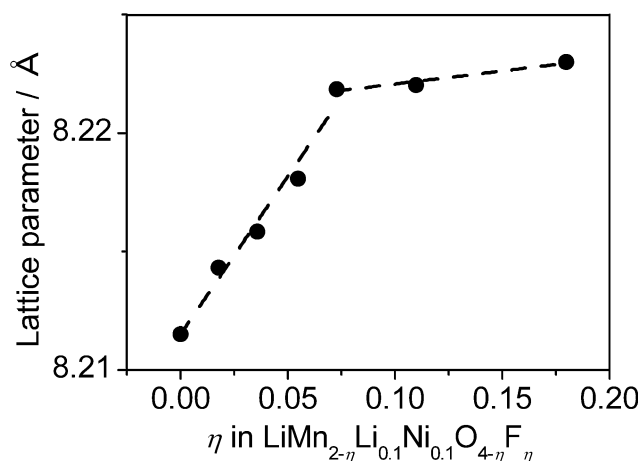

Fig. 4 Plots of lattice parameter against content of  $\text{F}^-$  in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.018, 0.036, 0.055, 0.073, 0.110, 0.180$ ).

increment of the  $\text{Ni}^{2+}$  ion content. Thus, the charge compensation with doping Ni ion occurred with the ratio change of  $\text{Mn}^{3+}/\text{Mn}^{4+}$  as well as  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$ .

Fig. 6 shows the Mn K-edge XANES spectra of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ). In the case of anion-substitution, the shape of Mn K-edge spectra did not depend on the composition  $\eta$  as well as  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$ , as Mn ions is considered to exist in the octahedral 16d site.<sup>26</sup> Contrary to the effect of cation-doping, the absorption edge shifted toward smaller energy levels with the increase of the  $\text{F}^-$  content. This result indicates that the charge compensation was carried by the reduction of  $\text{Mn}^{4+}$  to  $\text{Mn}^{3+}$  and the amount of  $\text{Mn}^{3+}$  increased. Hence, it was found that the  $\text{F}^-$ -substitution was effective to decrease the valence of Mn ion.

Next, the electronic structures of the cation ( $\text{Mn}^{3+/4+}$ ) and the anions ( $\text{F}^-$  and  $\text{O}^{2-}$ ) were investigated by the XANES analysis.

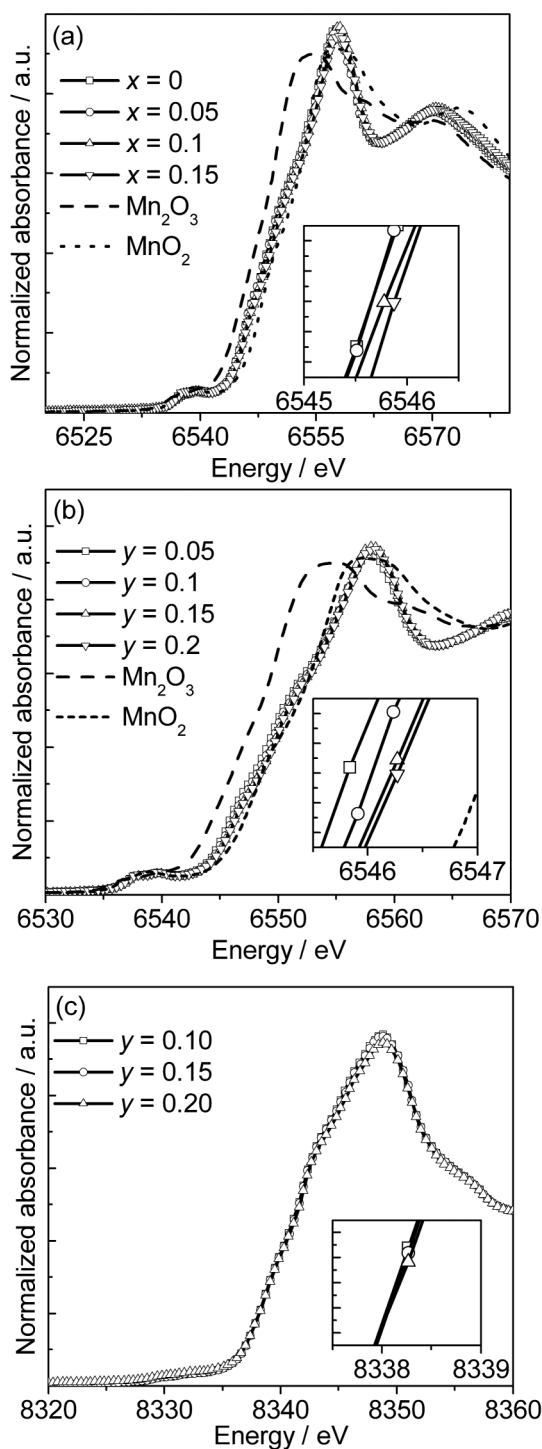

Fig. 5 XANES spectra of Mn K-edge of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) (a),  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) (b), and Ni K-edge of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.05, 0.10, 0.15, 0.20$ ) (c).

O K- and F K-edge XANES spectra were measured to consider the electronic structures in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ) since it was expected that the electronic structure of the hybridized orbital between Mn and O (or F) ions revealed the anion-substitution effect and the related phenomena. Fig. 7(a) and 7(b) show the O K- and F K-edge XANES spectra of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ). In the O K-edge

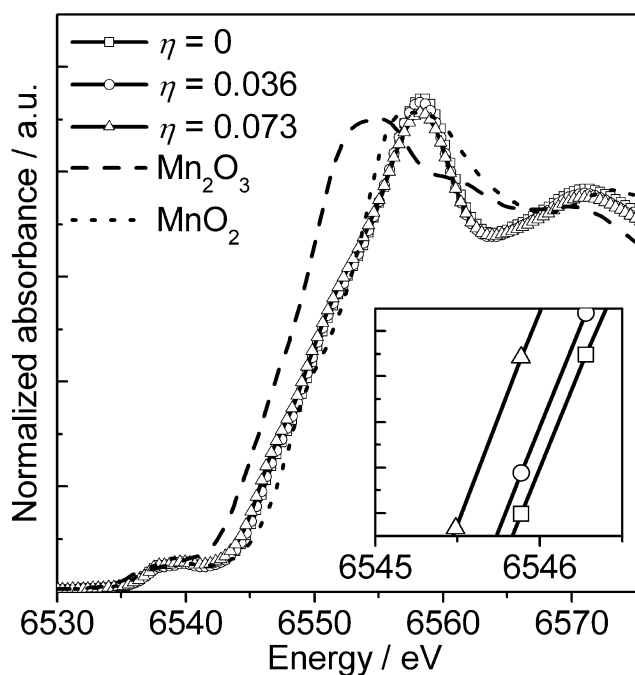

Fig. 6 XANES spectra of Mn K-edge of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ).

spectra, four peaks (A–D) were observed, corresponding to the transitions from O 1s core orbital to the unoccupied O 2p orbital with the dipole transition selection rules since the O 2p orbital was hybridized with the Mn 3d and 4sp orbitals. Therefore, the absorption peaks in O K-edge XANES reflect the ratio of unoccupied O 2p orbital connected with a Mn 3d and Mn 4sp orbital character.<sup>28</sup> The peaks A and B, which were observed around 526–534 eV, could be assigned to the transitions from O 1s orbital to the hybridized orbital between O 2p – Mn 3d  $t_{2g}$  and O 2p – Mn 3d  $e_g$ , respectively. The broad peaks (C and D around 524–546 eV) could be attributed to the transition from O 1s orbital to the hybridized orbital between O 2p and Mn 4sp orbitals.<sup>28</sup> The intensity of peak B increased with the increase of the F<sup>−</sup> content. This phenomenon would be interpreted as the increase in the hole state at the oxygen site, that is, the decrease in d electron donation from the Mn ion to the hybridized orbital. Based on this result, it is suggested that O<sup>2−</sup> was also associated with the charge compensation resulting from F<sup>−</sup> substitution and the nature of Mn–O bonding would be influenced by F<sup>−</sup> substitution. On the other hand, in the F K-edge spectra, there was no dependency on the F<sup>−</sup> content in the shape and absorption edge energy. This result indicates that the electron in the fluorine orbital was strongly localized.

The XANES spectra were measured also for the delithiated  $\text{LiMn}_2\text{O}_4$ -type compounds since the electronic structure of hybridized orbital between Mn and O ions would reveal the phenomena during lithium-ion deintercalation. The samples of the ex-situ XAS measurement were prepared during the first charge process and the lithium content of each sample is shown in Supporting Information.

The Mn K-edge XANES spectra of  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  at various charged states are shown in Fig. 8(a) and (b), respectively. The Mn ions occupied in the octahedral

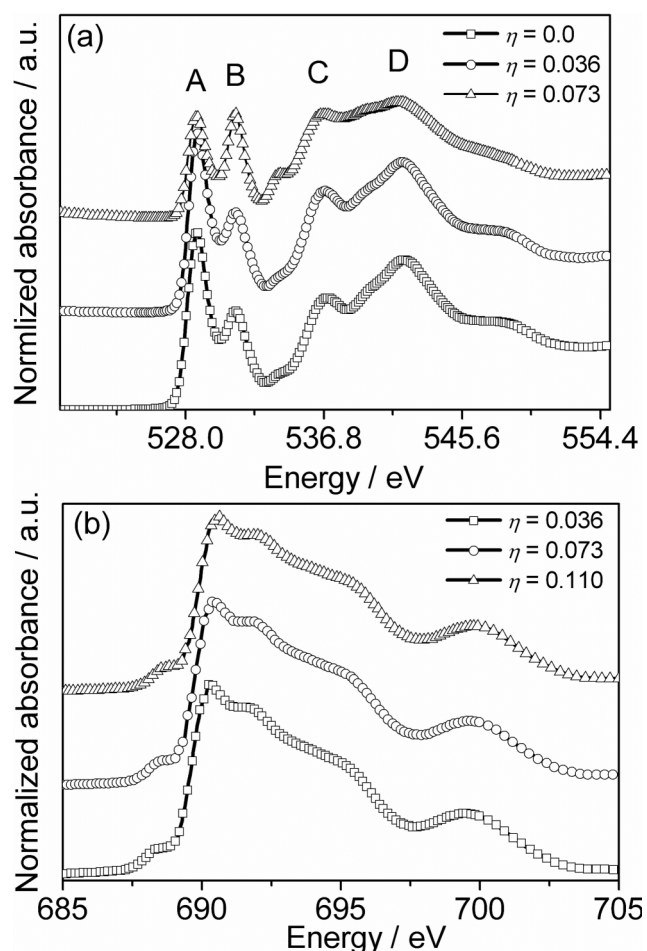

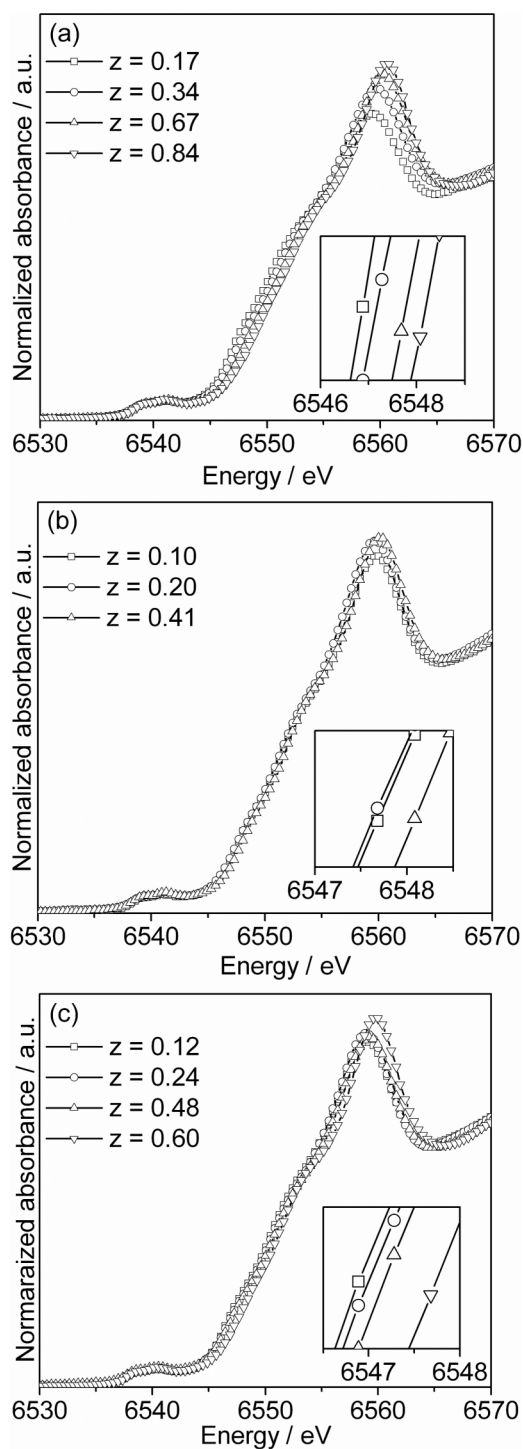

Fig. 7 XANES spectra of O K-edge (a) and F K-edge (b) of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073, 0.110$ ).

16d site were maintained during delithiated Li<sup>+</sup> ion since the shape of Mn K-edge spectra did not depend on the composition  $z$ . The absorption edge shifted toward large energy levels with decrease of the lithium ion content, which indicates that the amount of Mn<sup>4+</sup> increased. This result shows that the charge variation by lithium-ion extraction/insertion was compensated by the redox of Mn<sup>3+</sup>/Mn<sup>4+</sup> couple.

Fig. 9 shows the Mn L- and O K-edge XANES spectra of  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  at various discharged states. The Mn L-edge spectra for  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  (Fig. 9(a) and (c)) consist of two sets of peaks, L<sub>3</sub> (A, B) and L<sub>2</sub> (C) separated by *ca.* 10 eV. They correspond to the electronic transitions from the 2p<sup>3/2</sup> and 2p<sup>1/2</sup> sites to an unoccupied 3d state. The L<sub>2</sub>-edge peak C was more broadened than those of the L<sub>3</sub>-edge (A, B). This difference has been explained by Coster-Kronig Auger decay.<sup>29</sup> A shorter lifetime of the 2p<sup>1/2</sup> core hole due to a radiationless electron transition from the 2p<sup>2/3</sup> to the 2p<sup>1/2</sup> level, accompanies by the promotion of a valence electron into the conduction band. There were two peaks in the L<sub>3</sub>-edge since the Mn 3d orbital splits to  $t_{2g}$  (A) and  $e_g$  (B) states by the ligand field theory under octahedral ( $O_h$ ) symmetry.<sup>29</sup> The absorption edge shifted toward lower energy levels with the increase of  $z$  value, that is, the decrement of the lithium-ion content, indicating that number of Mn<sup>4+</sup> was increased by reduction of Mn<sup>3+</sup>. Focusing

**Fig. 8** Ex-situ XANES spectra of Mn K-edge for  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  (a)  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  (b) and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  (c) at various discharge state.

on the  $\text{L}_{2,3}$ -edge, the increase of peak A upon electrochemical lithium-ion extraction indicates that the electron is ejected from the occupied Mn 3d  $t_{2g}$  orbital, that is, the oxidation state of Mn ion increases. These results represent that the charge variation by the lithium-ion extraction was compensated by the redox of the  $\text{Mn}^{3+}/\text{Mn}^{4+}$  couple and the degree of hybridization between

Mn and oxide ions in  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  was influenced by the lithium-ion extraction process.

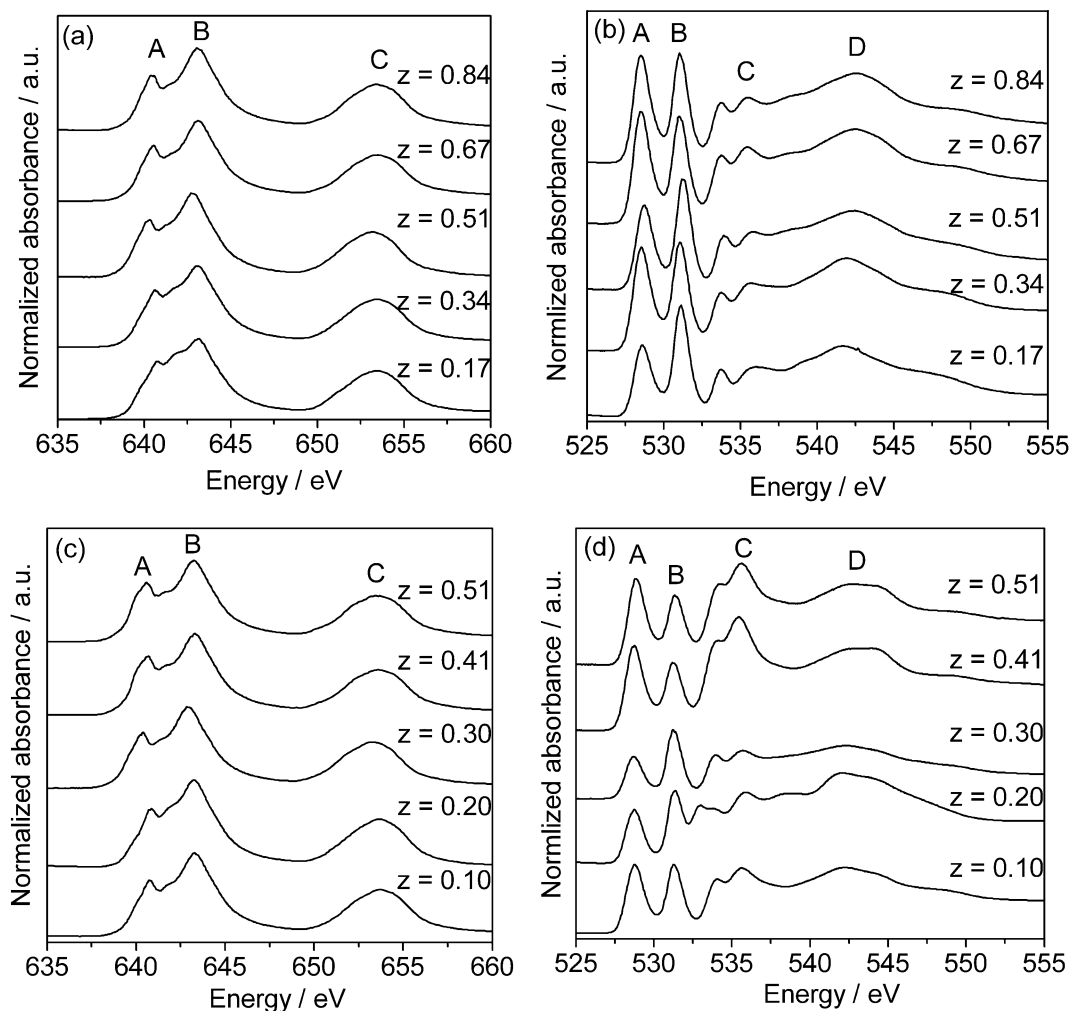

In the case of O K-edge spectra, four main peaks (A–D) were observed. Peaks A and B corresponded to the Mn 3d/O 2p hybridized orbital and peaks C and D were ascribed to the Mn 4sp/O 2p hybridized orbital, as described above. The intensity of peak A seems to increase with decrease of the  $\text{Li}^+$  ion content. This phenomenon would be interpreted that the electron is released from the Mn 3d/O 2p hybridized orbital, as the  $\text{Li}^+$  ion is extracted from the spinel manganese. A few peaks are observed in addition to the main four peaks in the O K-edge spectra of the delithiated samples. This would come from the reformation of the hybridized orbital between Mn and O ions. All the peaks dramatically change with the extraction of  $\text{Li}^+$  ion. Hence, it is considered that  $\text{O}^{2-}$  is also associated with the charge compensation during charge and discharge process. From the result of Mn L- and O K-edge XANES spectra, it was implied that electronic charge transfer processes occur at oxide ion sites as well as Mn ion sites in  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  upon electrochemical lithium-ion extraction. These combined results strongly suggest that these compounds are classified as the charge transfer type, which has been described for compounds containing late-transition metal ions.<sup>30–32</sup>

Fig. 10 shows the Mn L-, O K- and F K-edge XANES spectra of  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.864}\text{F}_{0.036}$  at various discharged states. The Mn L- and O K-edge spectra shown in Fig. 10(a) and (b) are essentially the same as those of the fluoride-free compounds shown in Fig. 9(a) and (b). It is accordingly expected that the peak assignment should be the same. The absorption edge shifted toward higher energy levels with the decrement of the lithium-ion content. This result indicates that number of  $\text{Mn}^{4+}$  is increased by the reduction of  $\text{Mn}^{3+}$ , which could also be observed at Mn K-edge XANES spectra (Fig. 8(c)). The increased intensity of peak B in Fig. 10(b) with delithiation suggests that the hole state at the oxygen site is increased with delithiation and thus the oxide ions contribute to the charge compensation during charge and discharge process. On the other hand, there is no dependency in the shape and absorption edge energy in the F K-edge spectra on delithiation. Note that, the XANES spectrum shapes of delithiated samples in Fig. 10(c) looks different from those of pristine ones in Fig. 7(b). It would be comes from the difference of background between both samples since the areas radiated active materials in delithiated samples were less as well as the amount of fluoride ion is small in the samples. This result indicates that the strongly localized fluoride orbital would not change during delithiation. From these results, it is implied that electronic transfer processes occur at oxide ion sites as well as Mn ion sites in  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.954}\text{F}_{0.036}$  as well as  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  upon electrochemical lithium-ion insertions. However, F 2p orbital is localized and do not effect on the electron exchange with lithium insertion/deinsertion.

### 3.3. Local structure

In order to investigate the local structures around Mn atom and Ni atom in  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$ ,  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  and  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$ , Mn and Ni K-edge EXAFS spectra were measured.

Fig. 11 (a) and (b) shows Fourier transforms (FTs) of the EXAFS oscillations in  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) and  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) which represent

**Fig. 9** Ex-situ XANES spectra of Mn L-edge (a) and O K-edge (b) for  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$ , and Mn K-edge (c) and O K-edge (d) for  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  at various discharge state.

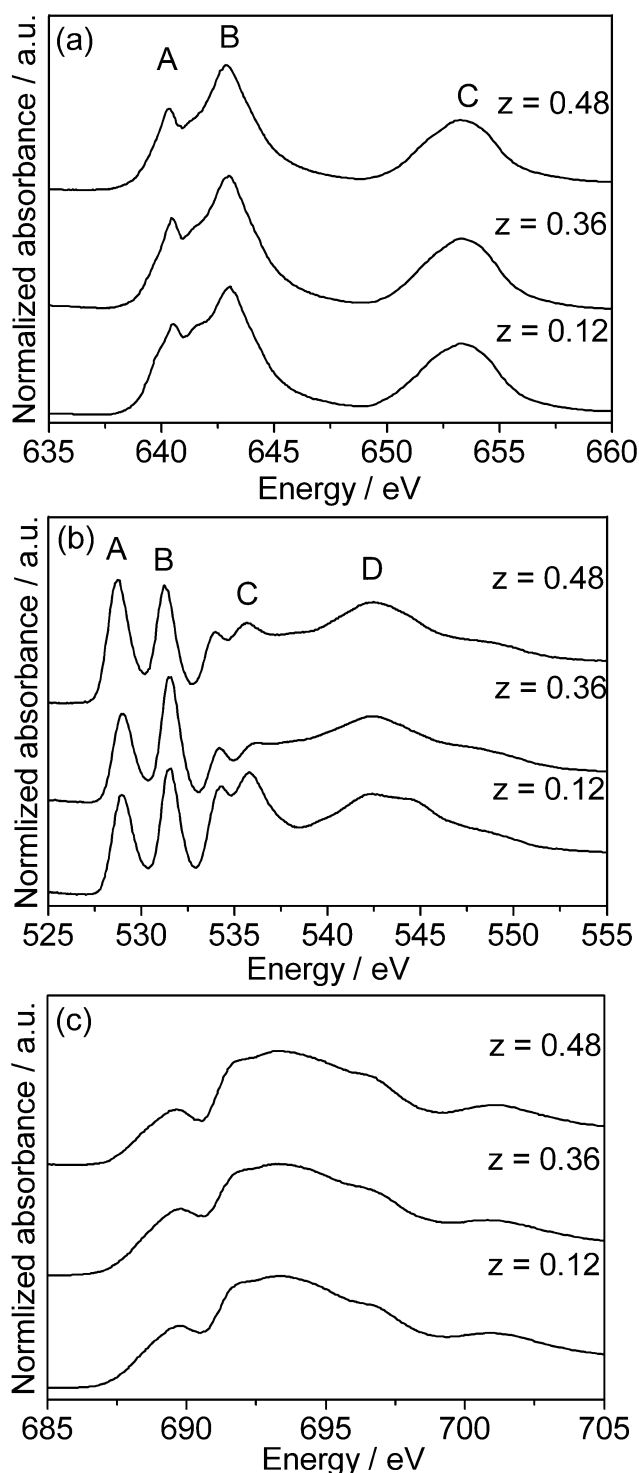

the pseudo-radial structure functions (RSFs) of the local atomic environments around the Mn atoms. The FTs of the  $k^3$ -weighted Mn K-edge EXAFS oscillations for samples were calculated within  $k = 3.5\text{--}14.0 \text{ \AA}^{-1}$  (this range was chosen to minimize noise). The RSFs of Mn K-edge EXAFS show two peaks at about 1.6 and 2.6  $\text{\AA}$ , respectively. The first and second peaks for the Mn K-edge spectra correspond to six coordinated Mn–O bonds in the  $\text{MnO}_6$  octahedron and Mn–M (Metal) interactions, respectively. As for the Mn–O peak, the intensity was increased with increasing the cation content in both spectra. The intensity of Mn–M peak for  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  did not show clear tendency while that for  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  was enhanced with increasing the Ni content.

The RSFs around the Mn atoms were inversely Fourier-filtered over the two peaks ( $R = 1.1\text{--}3.0 \text{ \AA}$ ) in the transformation and fitted with equation (1). The structural parameters were determined using curve-fitting, and the atomic distances and DW factors in  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  were compared with the  $x$  values as shown in Fig. 12. The bond length was decreased with the increase of  $\text{Li}^+$  ion content. This is due to the oxidation of Mn from  $\text{Mn}^{3+}$  to  $\text{Mn}^{4+}$ , which has already been indicated by the peak shift of Mn L-edge XANES. Shannon's ionic radius of  $\text{Mn}^{3+}$  and  $\text{Mn}^{4+}$  is 0.65  $\text{\AA}$  and 0.53  $\text{\AA}$ , respectively.<sup>25</sup> In addition, the inter-atomic lengths of

Mn–M decreased with the lithium-ion extraction. Hence,  $\text{MnO}_6$  octahedral would shrink with the increment of the  $\text{Li}^+$  ion content. This is also consistent with the XRD results. The DW factors for the Mn–O interaction decreased with the decrement of the lithium-ion content of the samples, indicating that the distortion of  $\text{MnO}_6$  octahedra decreased. The Jahn–Teller distortion of  $\text{Mn}^{3+}$  effects on this phenomenon. The DW factor for the Mn–M interaction was invariant with  $x$ . This phenomenon will be reconsidered below.

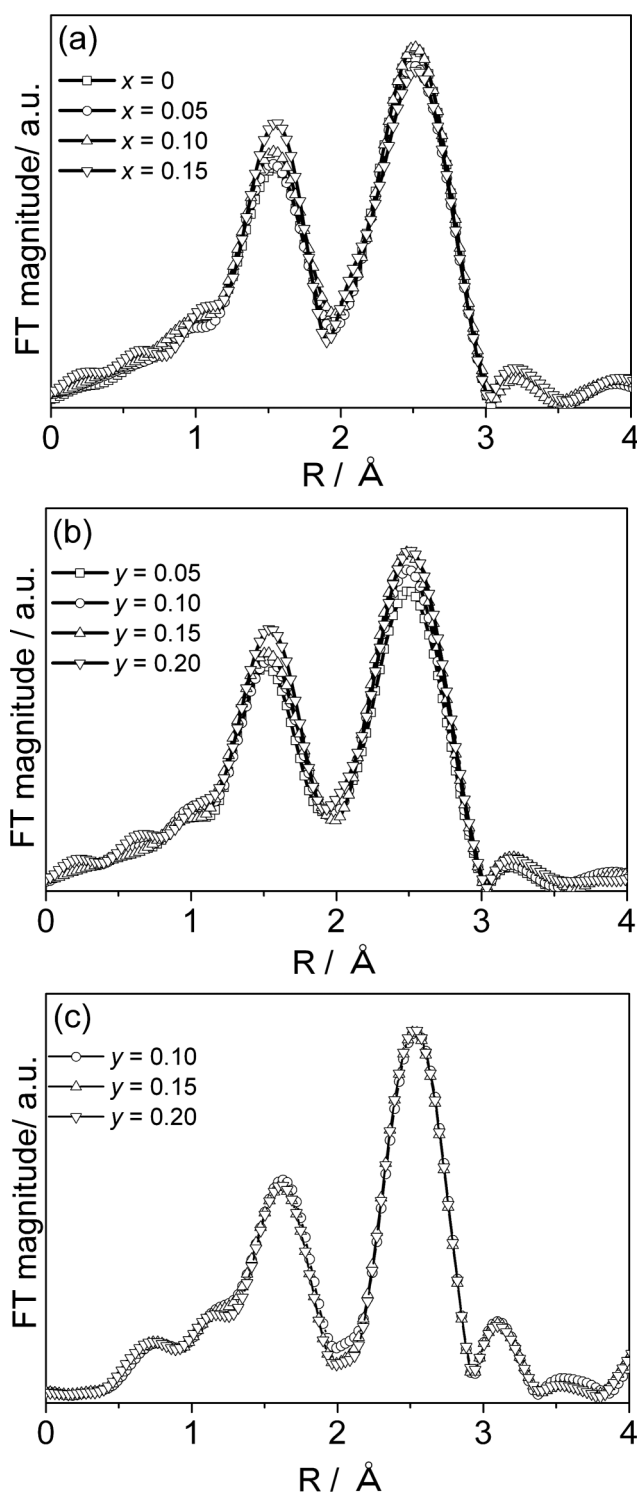

The same procedure was applied to  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  and the atomic distances and DW factors in  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  were compared with the  $y$  values as shown in Fig. 13. The Mn–O and Mn–M lengths were decreased with the increase of  $\text{Ni}^{2+}$  ion contents. This is due to the oxidation of Mn from  $\text{Mn}^{3+}$  to  $\text{Mn}^{4+}$ .

The DW factor for each interaction (Mn–O, Mn–Mn) decreased with the Ni substitution, indicating the decrement of the  $\text{MnO}_6$  octahedra distortion. For the local structure around Ni, there are no remarkable changes in the Ni K-edge spectra with the Ni content as shown in Fig. 11(c). As shown in Fig. 13, the Ni–O and Ni–M distance, as well as the DW factors, did not change with the Ni content. This reason would be that the doped Ni ion remained divalent at any Ni content. Based on these results, it is revealed that the local distortion around Mn was decreased by cation doping,

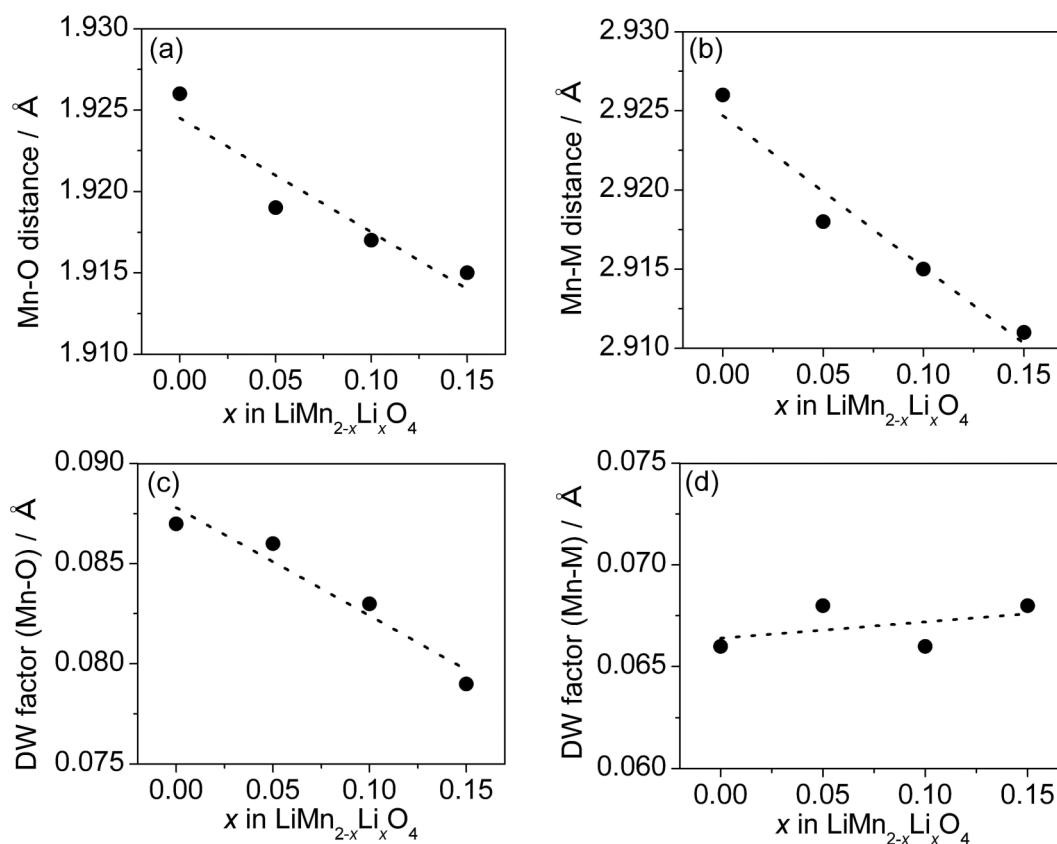

**Fig. 10** Ex-situ XANES spectra of Mn L-edge (a), O K-edge (b) and F K-edge for  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  at various discharge state.

since the number of  $\text{Mn}^{3+}$ , which is the Jahn–Teller cation, was decreased. The DW factor of Mn–M for  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  remained constant, but that for  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  was decreased with the increase of cation content. This difference is probably due to the fact that  $\text{Li}^+$  is larger than that of  $\text{Ni}^{2+}$ ; hence the influence of doped  $\text{Li}^+$  would not be observed at 2nd neighborhood for local distortion. Then, the influence of  $\text{F}^-$ -doping on the local structure

**Fig. 11** EXAFS spectra of Mn K-edge of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) (a) and  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) (b), and Ni K-edge of  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.10, 0.15, 0.20$ ) (c).

was investigated. Fig. 14 shows the FT of EXAFS oscillations of the Mn K-edge spectra of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.0, 0.036, 0.073$ ). The intensities of Mn–O(F) and Mn–M peaks were decreased with increasing of the  $\text{F}^-$  content. Fig. 15 shows the variation of interatomic distances and DW factors against the  $\text{F}^-$  content. The Mn–O(F) and Mn–M distances were monotonically

**Fig. 12** Plots of inter-atomic distances ((a) Mn–O and (c) Mn–M) and Debye–Waller (DW) factors ((b) Mn–O and (d) Mn–M) of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$  ( $x = 0, 0.05, 0.10, 0.15$ ) obtained by EXAFS analysis of Mn K-edge spectra.

increased with the increase of the  $\text{F}^-$  content due to the decrease of  $\text{Mn}^{4+}$  ion. The DW factors of both Mn–O(F) and Mn–M were increased, which indicated that local distortion around the Mn ion was increased. This is due to the increase of  $\text{Mn}^{3+}$  (Jahn–Teller) formed by the charge compensation. Based on the XAFS measurement, it was clarified that the effect of  $\text{F}^-$  substitution on the electronic/local structure was opposite to the low valence cation-doping.

The FTs of EXAFS oscillations of the Mn K-edge spectra of the delithiated  $\text{Li}_{1-x}\text{Mn}_2\text{O}_4$ ,  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  and  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  samples at various discharged states are shown in Fig. 16. The first and second peaks correspond to Mn–O and Mn–M bonds ( $\text{M} = \text{Mn, Li, and Ni}$ ), respectively. As for the Mn–O peak, the intensity was increased with decreasing of the  $\text{Li}^+$  ion content in these spectra. Fig. 17 shows the variation of interatomic distances and DW factors against the  $\text{Li}^+$  ion content. The Mn–O and Mn–M distance were monotonically decreased with decrease of the Li content due to the increase of  $\text{Mn}^{4+}$ . This result is corresponding to the decreased lattice parameters obtained from the XRD measurement. The DW factors of Mn–O were decreased monotonically with the decrease of  $\text{Li}^+$  ion contents. Based on the result, it was revealed that the local distortion around Mn ion was decreased by the extraction of  $\text{Li}^+$  ion, since the number of  $\text{Mn}^{3+}$ , which is Jahn–Teller cation, was decreased.

Next, we compare the degree of the DW factors for  $\text{Li}_{1-x}\text{Mn}_2\text{O}_4$ ,  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  and  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$ . The degree of the DW factor in  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  was smaller

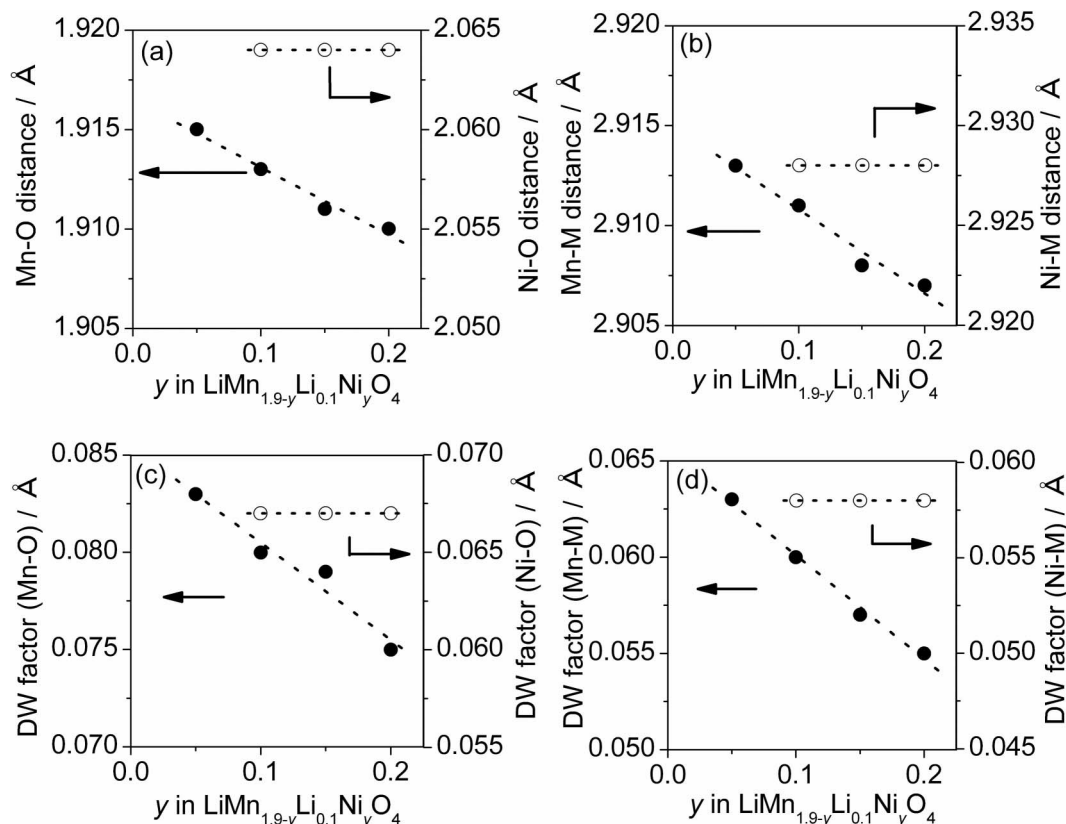

than that in  $\text{Li}_{1-x}\text{Mn}_2\text{O}_4$ . This is because of the smaller amount of the Jahn–Teller cation ( $\text{Mn}^{3+}$  ion) in the pristine  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  than  $\text{LiMn}_2\text{O}_4$ . On the other hand, the degree of the DW factor in  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  was similar to that in  $\text{Li}_{1-x}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ , although the amount of the  $\text{Mn}^{3+}$  ion in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  was greater than that in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ . It is considered that the  $\text{F}^-$  ion doping prevents the local distortion around Mn atom during the redox reaction ( $\text{Mn}^{3+}/\text{Mn}^{4+}$ ) in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$ .

Based on the ex-situ XAFS measurements, it was clarified that the structural relaxation with  $\text{F}^-$  ion doping is crucial to the local structural change during  $\text{Li}^+$  ion extraction as well as the amount of Jahn–Teller  $\text{Mn}^{3+}$  cations.

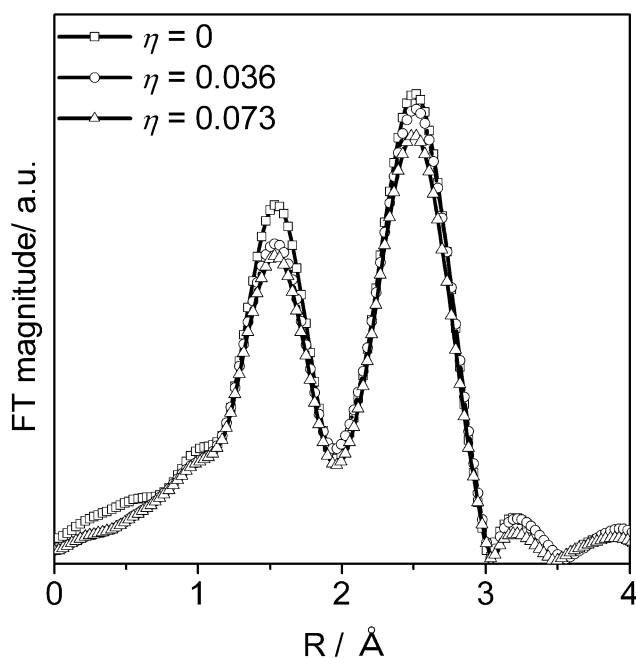

### 3.4. Electrochemical Properties

Fig. 18 shows the 1st charge and discharge curves of  $\text{LiMn}_2\text{O}_4$ ,  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ , and  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036, 0.073$ ). The order of the capacity was  $\text{LiMn}_2\text{O}_4 > \text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.073$ )  $>$   $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036$ )  $>$   $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ , which has been also reported before.<sup>33</sup> This order is corresponding to the number of  $\text{Mn}^{3+}$  in the pristine material obtained by the XANES results. Hence, it is confirmed that the increment of  $\text{Mn}^{3+}$  ion by the substitution of  $\text{F}^-$  ion is effective to increase the discharge capacity.

Fig. 19 shows the cycle performance of  $\text{LiMn}_2\text{O}_4$ ,  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ , and  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036$ ). Although  $\text{LiMn}_2\text{O}_4$  showed a large capacity at early cycles, the

**Fig. 13** Plots of inter-atomic distances ((a) Mn–O (closed cycle) and Ni–O (open cycle), (c) Mn–M (closed cycle) and Ni–M) and Debye–Waller (DW) factors ((b) Mn–O (closed cycle) and Ni–O (open cycle), (d) Mn–M (closed cycle) and Ni–M (open cycle)) of  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  ( $y = 0, 0.05, 0.1, 0.15, 0.2$ ) obtained by EXAFS analysis of Mn and Ni K-edge spectra.

**Fig. 14** EXAFS spectra of Mn K-edge of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ).

capacity decreased rapidly. On the contrary,  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  showed a small capacity but good cycleability. This result is

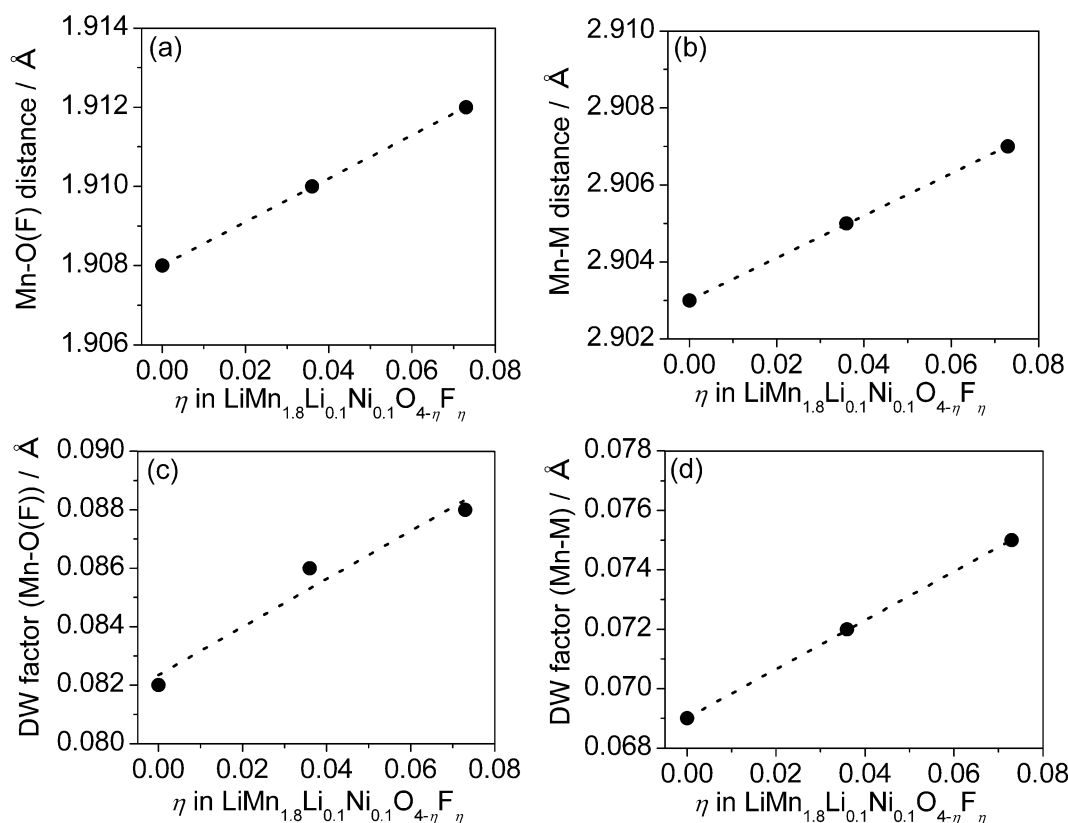

explained as follows. For  $\text{LiMn}_2\text{O}_4$ , a large distortion of the  $\text{MnO}_6$  octahedrons, which were shown as the Debye–Waller factors in Fig. 17, is responsible for the insufficient cycle performance. Low valence cation-doping in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  imparts the cycleability by the decrease of the local distortion of Jahn–Teller  $\text{Mn}^{3+}$  ion.

A relatively high capacity were fortunately obtained in  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036$ ). The large capacity results from the increment of the  $\text{Mn}^{3+}$  ion. Moreover, a relatively good cycleability was also observed, while the increment of Jahn–Teller  $\text{Mn}^{3+}$  ion is deemed as the problem for cycleability. The  $\text{F}^-$  ion doping could prevent the  $\text{MnO}_6$  octahedra distortion and thus serve the improvement in cycleability.

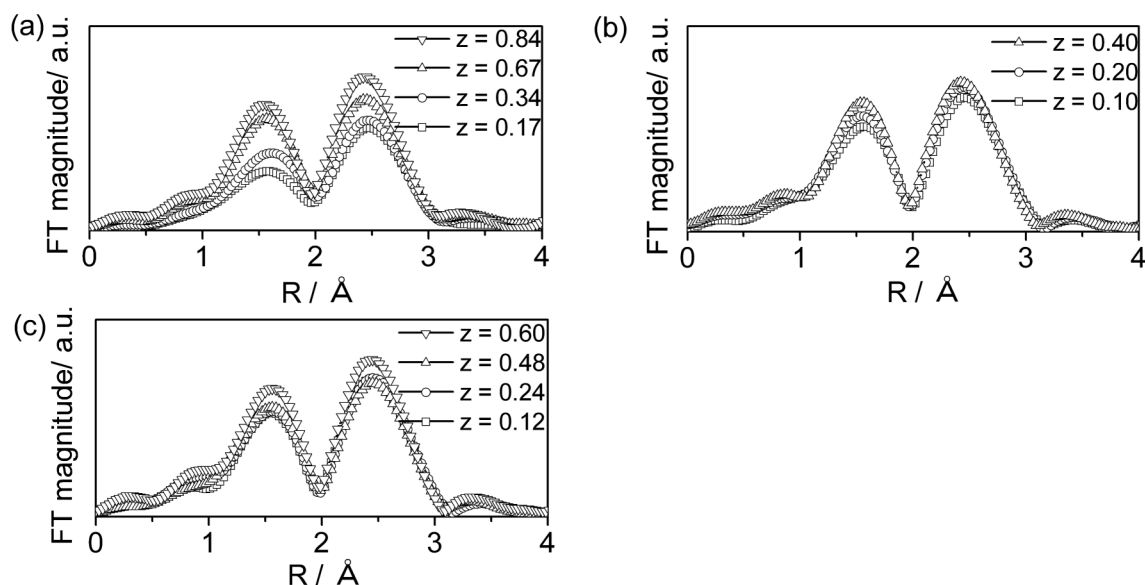

In order to improve the electrochemical performance of the spinel lithium manganese oxides, anion substitution would be one of the effective methods when combined with low valence cation-doping.

## Conclusions

In order to clarify the effect of anion-substitution for spinel lithium manganese oxides on the electrochemical performance, the electronic and local structures of  $\text{LiMn}_{2-x}\text{Li}_x\text{O}_4$ ,  $\text{LiMn}_{1.9-y}\text{Li}_{0.1}\text{Ni}_y\text{O}_4$  and  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  were investigated using X-ray absorption spectroscopy. The atomic distance between Mn and O was decreased with the increase of doped low valence cation (Li or Ni) content. This is due to the increase of  $\text{Mn}^{4+}$  formed by charge

**Fig. 15** Plots of atomic distances ((a) Mn–O(F) and (c) Mn–M) and Debye–Waller (DW) factor ((b) Mn–O(F) and (d) Mn–M) of  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0, 0.036, 0.073$ ) obtained by EXAFS analysis of Mn K-edge spectra.

**Fig. 16** Ex-situ EXAFS spectra of Mn K-edge for  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  (a),  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  (b) and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  (c) at various discharge state.

compensation (oxidation of  $\text{Mn}^{3+}$  to  $\text{Mn}^{4+}$ ). The local distortion around Mn ion was decreased, since the number of  $\text{Mn}^{3+}$ , which is a Jahn–Teller ion, was decreased. On the contrary, the distance between Mn and O(F) was increased with increase of  $\text{F}^-$  content. This is due to the increase of  $\text{Mn}^{3+}$  formed by charge compensation (reduction of  $\text{Mn}^{4+}$  to  $\text{Mn}^{3+}$ ).

The charge and discharge performance is strongly related with electronic structure around Mn ion, and  $\text{F}^-$  ion substitution makes the capacity increment. Furthermore, the degradation of cycleability with the effect of Jahn–Teller  $\text{Mn}^{3+}$  ion could be prevented by the  $\text{F}^-$  ion substitution. Therefore, designation of suitable anion substitution and low valence cation-doping

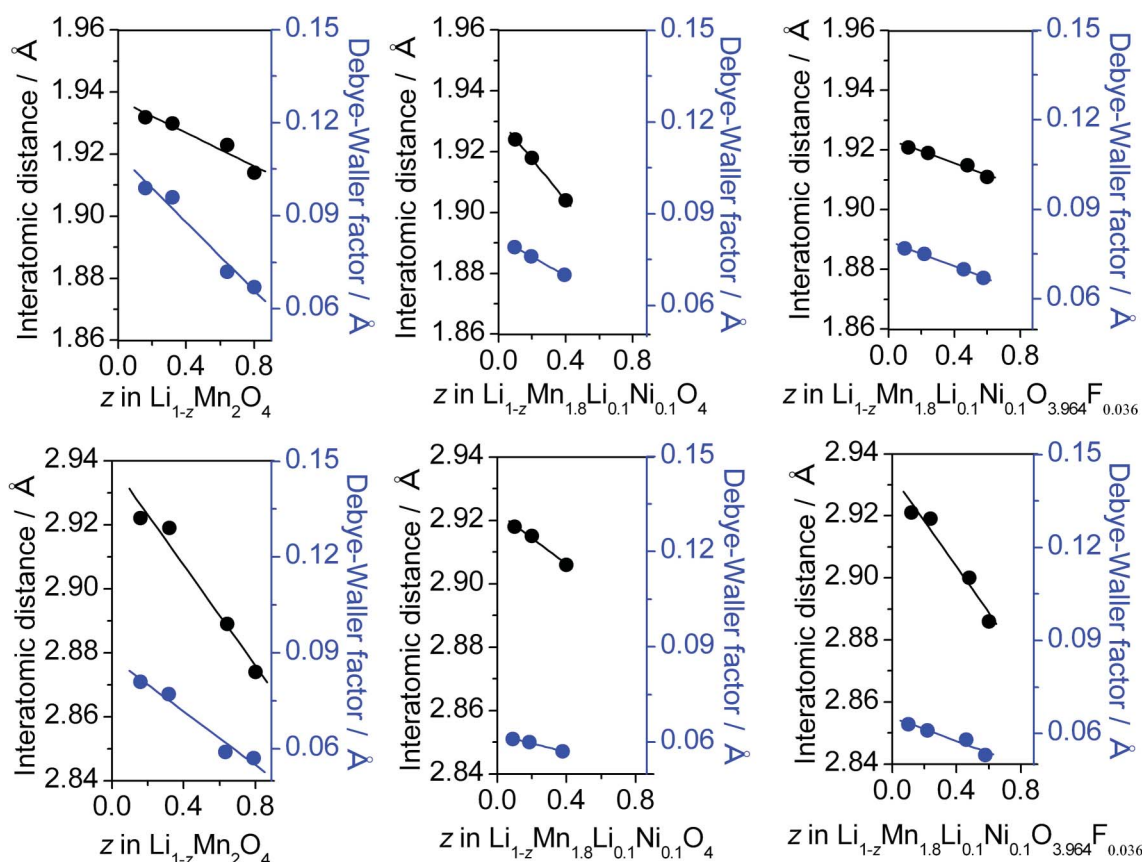

Fig. 17 Plots of inter-atomic distances and Debye–Waller (DW) factors of (Mn–O, F and Mn–M) of  $\text{Li}_{1-z}\text{Mn}_2\text{O}_4$  (a, d),  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$  (b, e) and  $\text{Li}_{1-z}\text{Mn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{3.964}\text{F}_{0.036}$  (c, f) at various discharge states.

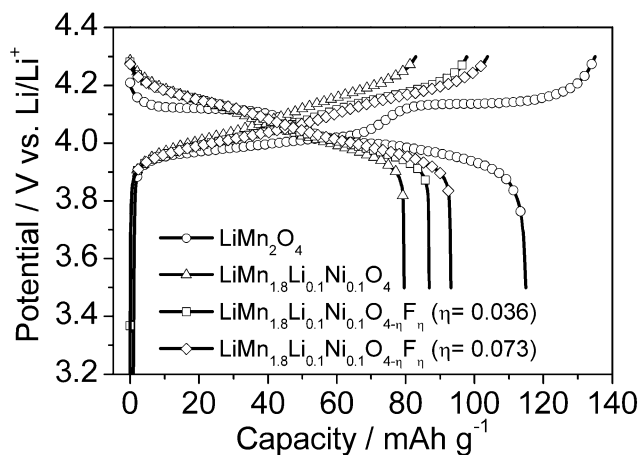

Fig. 18 Charge and discharge profile at 1st cycle of  $\text{LiMn}_2\text{O}_4$ ,  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_4$ , and  $\text{LiMn}_{1.8}\text{Li}_{0.1}\text{Ni}_{0.1}\text{O}_{4-\eta}\text{F}_\eta$  ( $\eta = 0.036, 0.073$ ).

should be effective for realizing higher electrochemical performance.
